CHAPTER 1.2.11

Listeria monocytogenes and the Genus *Listeria*

NADIA KHELEF, MARC LECUIT, CARMEN BUCHRIESER, DIDIER CABANES,
OLIVIER DUSSURGET AND PASCALE COSSART

Introduction

The genus *Listeria* contains six species, two of which are pathogenic: *Listeria monocytogenes*, the food-borne human pathogen responsible for listeriosis, on which this chapter is focused, and *L. ivanovii*, an animal pathogen. Listeriae are Gram-positive rod-shaped bacteria with low G+C content, which are found in a variety of animals and niches, including processed food. They are resistant to extreme conditions, such as low temperature or high salt, demonstrating a great adaptability to their environment (Vazquez-Boland et al., 2001).

Listeria monocytogenes infections cause gastroenteritis, meningitis, neuro-encephalitis, chorioamnionitis, abortions, and neonatal infections. Listeriosis is associated with a high mortality rate, particularly in immunocompromized individuals (Schlech, 2000). In addition to its medical importance, *L. monocytogenes* contamination of food products raises important economic issues in the food industry.

Listeria monocytogenes is a facultative intracellular pathogen. It has evolved a panoply of virulence factors, which exploit important cellular processes during infection (Cossart et al., 2003; Cossart and Sansonetti, 2004). *Listeria monocytogenes* has emerged as a genetically manipulable tool to address key cell biology processes, such as phagocytosis, actin-based motility and signaling through growth factor receptors (Cameron et al., 2000; Cossart and Bierne, 2001; Bierne and Cossart, 2002a). Moreover, as a result of its intracellular life, *L. monocytogenes* mediates a strong T-cell response and is widely used as a model to study the CD8-mediated immunity of intracellular parasites (Edelson and Unanue, 2000; Badovinac et al., 2003; Lara-Tejero and Pamer, 2004). The detailed mechanisms of the immune response to *L. monocytogenes* will not be treated in this review, as they are elegantly and largely reviewed (Edelson and Unanue, 2000; Unanue, 2002; Badovinac et al., 2003; Lara-Tejero and Pamer, 2004, Pamer, 2004). The combined use of genetics, cell biology, functional genomics and post-sequencing studies has led to a precise understanding of *L. monocytogenes* infections. Comparative genomics of *L. monocytogenes* with the nonpathogenic species *L. innocua*, and other *Listeria* species can now be fully exploited for the study of virulence, regulation and biodiversity of Listeriae (Glaser et al., 2001; Cabanes et al., 2002; Buchrieser et al., 2003; Doumith et al., 2004a).

The Discovery of Listeriosis and Listeriae

Listeriosis was first described in the late 1920s and proposed to be contracted through oral contamination. This hypothesis was confirmed in the 1960s. A series of outbreaks in industrialized countries during the 1970s and 1980s definitely established that *L. monocytogenes* was indeed responsible for food-borne listeriosis (Schlech, 1984; Rocourt and Cossart, 1997).

The first official strain of the human pathogen *L. monocytogenes* was isolated in 1924 after an animal carehouse outbreak among rabbits and guinea pigs exhibiting severe mononucleosis (Murray et al., 1926). A clinical isolate of *L. monocytogenes* from a case of human meningitis was deposited at the Institut Pasteur in 1921 (Dumont and Cotoni, 1921). The first strain of the animal pathogen, *L. ivanovii*, was identified in the 1960s from lambs with congenital listeriosis (Ivanov, 1962).

Classification

Listeria spp. are small Gram-positive, nonspore forming, noncapsulated bacilli, generally motile at low temperatures (20°C), although some *Listeria* strains are nonmotile at 37°C because of lack of flagellin expression at this temperature (Way et al., 2004). Their DNA is characterized by a low G+C content (36–42%). They are related to *Clostridium*, *Bacillus*, *Enterococcus*, *Streptococcus* and *Staphylococcus* (Seeliger and Jones, 1986; Schmid et al., 2005). On the basis of DNA-

DNA hybridization, multi-locus enzyme electrophoresis (MEE), rRNA gene restriction patterns, and 16S rRNA sequencing, the genus *Listeria* comprises six species and two subspecies: *L. monocytogenes*, *L. ivanovii* subsp. *ivanovii*, *L. ivanovii* subsp. *londoniensis*, *L. seeligeri*, *L. innocua*, *L. welshimeri* and *L. grayi*. *Listeria monocytogenes* is a human and animal pathogen, and *L. ivanovii* is pathogenic for animals, mainly sheep and cattle. On rare occasions, *L. ivanovii* and *L. seeligeri* were shown to be associated with human infections (Rocourt and Cossart, 1997; Schmid et al., 2005).

Isolation and Characterization

Reservoirs

Listeriae are found in a wide variety of reservoirs ranging from soil, rotting plants, water, cattle milk and food to numerous animal species and humans. There is an asymptomatic carriage of *L. monocytogenes* in the intestinal tract (Seeliger and Jones, 1986; Grif et al., 2001). Listeriae can also colonize various inert surfaces and can form biofilms on food-processing surfaces (Roberts and Wiedman, 2003).

Detection and Isolation

Isolation of *Listeria* from contaminated or infected material can be obtained by direct plating on tryptic soy base agar supplemented with blood for human samples, but an enrichment step followed by plating on selective media is recommended for polycontaminated samples, such as food products. Enrichment procedures vary but are generally based on a one- or two-step enrichment in liquid selective broth, followed by plating on selective solid media, which allow identification of Listeriae (LPM, Oxford, or PALCAM agar), or specific identification of *L. monocytogenes* strains (Rapid L. Mono, ALOA [Agar *Listeria* Ottavani and Agosti], and Chromagar) (Figs. 1 and 2). Rapid detection of Listeriae in food isolates, for example, can be performed using immunoassay-based kits. However, PCR (polymerase chain reaction) is the technique of choice for rapid detection of *L. monocytogenes* in both clinical and food isolates. Isolation remains indispensable for epidemiological studies (Swaminathan et al., 1995; Allerberger, 2003).

Identification

Genus identification is based on classical tests including Gram staining, observation of motility, and biochemical reactions, such as catalase and acid production from D-glucose (Swaminathan
Fig. 1. *Listeria* spp. grown on RAPID'L. MONO medium. *Listeria monocytogenes* appears as blue colonies while other *Listeria* spp. appear as white colonies. Reproduced with permission from BIO-RAD, Marnes La Coquette, France.

et al., 1995). Identification of *Listeria* spp. is based on a few biochemical markers and on hemolysis (Table 1). *Listeria* spp. can be identified using an API-*Listeria*® test, a set of 10 biochemical tests, including arylamidase, which discriminates pathogenic *L. monocytogenes* from nonpathogenic *L. innocua* (Swaminathan et al., 1995) (Fig. 3). Hemolysis is produced by *L. monocytogenes* but also by *L. ivanovii* and *L. seeligeri*. Hemolysis of *L. monocytogenes* is narrow and does not develop beyond the edge of colonies. It is due to listeriolysin O (LLO), a β-hemolysin known to be a major virulence factor. Hemolysis of *L. ivanovii* is wider, often bizonal, with a first ring of complete hemolysis and a

second ring of incomplete hemolysis. *Listeria seeligeri* is weakly hemolytic (Fig. 4). Hemolysis of *L. ivanovii* and *L. seeligeri* is due to listeriolysin homologues, ivanolysin O and seeligerolysin O, respectively, and for *L. ivanovii* to the sphingomyelinase SmcL (Leimeister-Wachter and Chakraborty, 1989; Vazquez-Boland et al., 1989; Haas et al., 1992; Gonzalez-Zorn et al., 1999). The natural hemolysis of Listeriae is specifically enhanced by the products released by other hemolytic bacteria, *Staphylococcus aureus* for *L. monocytogenes* and *L. seeligeri*, or *Rhodococcus equi* for *L. ivanovii* in the CAMP test (Christie, Atkins, Munch-Petersen). In this assay, the streaking of Listeriae and *S. aureus* or *Rhodococcus equi* in close proximity and perpendicularly gives rise to a characteristic shovel-shaped patch of synergistic hemolysis (Swaminathan et al., 1995). In *L. ivanovii*, the bizonal hemolysis and the effect observed in the CAMP test are due to the SmcL phospholipase (Gonzalez-Zorn et al., 1999) (Fig. 5).

Other approaches, such as growth on chromogenic selective media, Rapid L-mono, or ALOA, allow identification of *L. monocytogenes*. Identification on Rapid L-mono plates is based on chromogenic detection of phosphatidylinositol (PI) phospholipase C (PLC-A) and on xylose fermentation differentially produced by *Listeria* species. *Listeria monocytogenes* appears as blue colonies (phospholipase C [PLC] positive) without halo (xylose negative), while *L. ivanovii* appears as blue colonies surrounded by a yellow halo (PLC and xylose positive). Other *Listeria* species appear as white colonies. In addition, chemiluminescent DNA probe assays allow rapid confirmation of *L. monocytogenes* from primary isolation colonies. Finally, sequencing of the 16S rRNA, ribotyping, or pulsed-field gel electrophoresis (PFGE), can be used as an identification method for species determination or subdivision within species (Brosch et al., 1996; Allerberger, 2003).

Typing

Although different methods are available to characterize isolates *L. monocytogenes* [phage typing,

ribotyping, DNA macro-restriction analysis, random amplified polymorphic DNA (RAPD) and multi-locus enzyme electrophoresis (MEE)], serotyping and DNA macro-restriction analysis are methods of choice for outbreak investigations. The 16 serovars of *Listeria* are based on the expression of somatic (O) and flagellar (H) antigens (Table 2), with 13 *L. monocytogenes* serovars that can cause disease. Approximately 95% of the human isolates belong to serovars 4b, 1/2a, and 1/2b. Strikingly, serovars 4b are found in most of the invasive foodborne outbreaks worldwide and in up to 50% of the sporadic cases of listeriosis, while serogroups 1/2 (including 1/2a, 1/2b and 1/2c) are mostly associated with sporadic cases (Rocourt and Cossart, 1997). More recently, multiplex PCR was proposed as an alternative to serotyping (Doumith et al., 2004b). The method allows to differentiate the major serovars, 1/2a, 1/2b, 1/2c and 4b, of *L. monocytogenes*.

Techniques based on phenotypic differentiation (phage typing and bacteriocinotyping) or on molecular characterization (MEE and DNA typing methods) were developed to further characterize strains of the same serovar. Phage typing is based on the testing of the isolates for their sensitivity to a set of phages isolated from lysogenic *Listeria* strains. MEE allows the determination of a pattern of enzyme activities that are specific for *Listeria* subtypes. Both techniques have been successfully applied for epidemiological studies. Molecular methods, such as characterization of chromosomal DNA by restriction endonuclease analysis, ribotyping, RAPD, or PFGE are also used to type *Listeria* strains. PFGE is the most discriminatory method to identify *L. monocytogenes* and is recommended, together

with serotyping, for epidemiological surveillance (Swaminathan et al., 1995; Brosch et al., 1996).

Serodiagnosis and Determination of Pathogenicity

Serologic tests cannot be used directly for diagnosis because of an antigenic cross-reactivity between *L. monocytogenes* and other Gram-positive bacteria (Swaminathan et al., 1995). However, detection of anti-listeriolysin antibodies, after adsorption on streptolysin O of *Streptococcus pyogenes*, is a good indicator of infection (Berche et al., 1990). Determination of the pathogenicity of Listeriae in animal models is not used routinely for identification (Swaminathan et al., 1995).

Physiology

Growth Conditions: pH, Temperature and Salts

Listeriae are facultative anaerobic bacteria, a property that might be advantageous during infection. They grow perfectly well in laboratory aerobic conditions. Although BHI (brain heart infusion) is the medium of choice for growth in vitro, Listeriae can grow in several other media such as Luria broth (LB). A minimal medium previously used (Premaratne et al., 1991) was recently readapted based on the analysis of the genome sequence of *L. monocytogenes* (Tsai and Hodgson, 2003). One of the key properties of *L. monocytogenes* resides in its ability to grow in a wide range of temperatures (1–45°C), which favors resistance and enrichment in foods. However, optimal growth occurs at 30–37°C. Listeriae are killed at 60°C, making pasteurization a good technique to eliminate the bacteria from dairy products (Seeliger and Jones, 1986). Analysis of *L. monocytogenes* grown at different temperatures and of cold-sensitive mutants revealed that temperature adaptation involves modifications of the fatty acid composition of the bacterial membrane (Annous et al., 1997). Listeriae also resist relatively extreme pH and salt conditions (pH 4.5–9 and 10% NaCl), but optimal growth occurs at neutral pH and 0.5% NaCl (McClure et al., 1991). The striking resistance of Listeriae to harsh external conditions accounts for its wide distribution in multiple habitats and explains the increasing numbers of food-borne outbreaks in industrialized countries.

Nutrients

Carbohydrates, amino acids (cysteine, glutamine, isoleucine, leucine and valine) and vitamins (biotin, riboflavin, thiamine and thioctic acid) are required for *Listeria* growth (Seeliger and Jones, 1986). An extensive study of the behavior of several auxotrophic mutants revealed that threonine, adenine or phenylalanine–tryptophan-tyrosine auxotrophs were less virulent (Marquis et al., 1993). Iron and some amino acids (arginine, histidine, methionine and tryptophan) stimulate *L. monocytogenes* growth. Activated charcoal or cellobiose have no effect on growth but modulate the expression of virulence genes (Cowart and Fosters, 1985; Seeliger and Jones, 1986; Park and Kroll, 1993; Ripio et al., 1996; Huillet et al., 1999).

Inhibitory Agents and Antibiotics

Virulent *Listeria* strains are resistant to bile (up to 40%) on agar plates. This is partly due to the expression of a bile salt hydrolase, encoded by the *bsh* gene (Dussurget et al., 2002) and other bile tolerance genes encoded by the locus *btlA* (Begley et al., 2003). Disinfectants are active on Listeriae allowing efficient treatment of surfaces in contact with food, but serum and milk reduce their bactericidal activities, emphasizing the attention drawn to hygiene in food industries (Best et al., 1990).

While antibiotic sensitivity might vary between strains, most Listeriae are sensitive to many antibiotics, such as aminoglycosides, tetracyclines, macrolides, chloramphenicol and penicillins. Some of them are used to treat listeriosis, e.g., usually ampicillin in combination with an aminoglycoside (Charpentier et al., 1995; Hof et al., 1997; Troxler et al., 2000). *Listeria* strains are naturally resistant to antibiotics such as cephalosporins or sulfonamides. Resistance to nalidixic acid is exploited to enrich samples in *L. monocytogenes*, and most enrichment media contain this antibiotic. Although antibiotic resistance of Listeriae is not yet a concern for clinics, new tetracycline- or trimethoprim-resistant strains have recently emerged (Poyart-Salmeron et al., 1990; Poyart-Salmeron et al., 1992; Charpentier et al., 1995; Charpentier and Courvalin, 1999).

The Human Disease: Epidemiological and Clinical Aspects

Epidemiology

Listeria monocytogenes had been isolated in humans as early as the 1920s (Murray et al., 1926; Pirie, 1927). Nevertheless, it was not identified as an important cause of neonatal infection until after World War II in Germany (Potel, 1952). The

development and use of immunosuppressive agents in the second half of the twentieth century led to the identification of listeriosis cases in immunocompromized patients (Louria et al., 1967). Subsequently, the development of highly immunosuppressive therapies for organ or bone marrow transplantations led to a great expansion of the immunocompromized population and the subsequent identification of immunosuppression as a major risk factor for listeriosis (Stamm et al., 1982). More recently, the human immunodeficiency virus (HIV) epidemic has markedly enlarged the immunodeficient population, with a relative risk of developing listeriosis 500 times higher in acquired immunodeficiency syndrome (AIDS) patients as compared to the general population (Jurado et al., 1993). Globally, human listeriosis remains a rare disease, and its prevalence is declining in industrialized countries in which food control measures have been implemented. The attack rate is considered to be around 7 per million, leading to 2500 cases and around 500 deaths per year in the United States (Gellin et al., 1991; Lorber, 1997; Vazquez-Boland et al., 2001; Wing and Gregory, 2002). Infection is more common in children (100 cases per million) and elderly (14 cases per million). Pregnant women are 20 times more likely to develop listeriosis than the general population (Broome, 1993).

It has been observed very early in ruminants that oral ingestion of *L. monocytogenes* was associated with listeriosis (Low and Renton, 1985). This led to the hypothesis that *L. monocytogenes* was also a human foodborne pathogen. However, not until the 1980s was the validity of this hypothesis formally demonstrated, and it has now been widely confirmed by other investigators (Schlech et al., 1983). A number of listeriosis outbreaks and sporadic cases consequent to the ingestion of contaminated food products have been reported, as well as the origin of contamination (Table 3). Indeed, vegetables can become contaminated from the soil or from manure used as fertilizer, and animals can carry the bacterium asymptomatically and contaminate foods of animal origin, such as meats and dairy products. *Listeria monocytogenes* is found in a variety of raw foods, such as uncooked meats and vegetables, or processed foods that become contaminated after processing, such as soft cheeses and cold cuts at deli counters (Fleming et al., 1985; Linnan et al., 1988; Schwartz et al., 1989; Riedo et al., 1994; Bula et al., 1995; Salamina et al., 1996; Dalton et al., 1997; Goulet et al., 1998; Aureli et al., 2000; Ooi et al., 2005). Unpasteurized milk or foods made from unpasteurized milk may contain the bacterium. *Listeria monocytogenes* is killed by pasteurization and cooking. However, in certain ready-to-eat foods such as hot dogs and deli meats, contamination may occur after cooking before packaging. Government agencies and the food industry have taken steps to reduce contamination of food by *L. monocytogenes*. The United States Food and Drug Administration (FDA) (http://www.fda.gov/) and the United States Department of Agriculture (USDA) (http://www.usda.gov) monitor food regularly. When a processed food is found to be contaminated, food monitoring and plant inspection are intensified, and if necessary, the implicated food is recalled (for details, see the web sites of the World Health Organization (http://www.who.int/foodsafety/en/), Centers for Disease Control and Prevention (CDC) (http://www.cdc.gov), (http://www.foodsafety.gov/~fsg/fsgprobs.html{Gateway to Government Food Safety Information} or http://www.afssa. fr{Agence française de sécurité sanitaire des aliments}).

Most human foodborne infections are associated with high prevalence but low morbimortality. The situation is different for human listeriosis, which is a rare but very serious infec-

Table 3. Main listeriosis outbreaks in Europe and the United States.

Year	Location	Number of cases	Perinatal cases (%)	Mortality rate (%)	Source of contamination
1980–1981	Canada	41	83	34	Cole slaw

[a]Rilettes, a spread similar to paté, usually made of pork.

tion, associated with a mortality of up to 30%, even when an adequate treatment is administered. This accounts for the high economic impact associated with listeriosis despite its relative low prevalence (Table 4). Moreover, listeriosis remains under-diagnosed, particularly at its early stages, and this leads to delay in the administration of antimicrobial therapy, which is absolutely critical for a favorable outcome, contrary to most other foodborne infections (Lorber, 1997; Wing and Gregory, 2002). More detailed informations concerning epidemiology can be found at http://www.cdc.gov/ncidod/dbmd/ diseaseinfo/listeriosis_t.htm; http://www.who.int/ foodsafety/micro/jemra/assessment/listeria/en/; http://www.invs.sante.fr/beh/2004/09/index.htm.

Clinical Manifestations

Listeria monocytogenes infects humans through the ingestion of contaminated food products. The bacteria can cross the intestinal barrier and disseminate from the mesenteric lymph nodes to the spleen and the liver, from which they may reach the brain or the placenta, resulting in meningitis or encephalitis in immunocompromized patients, abortions in pregnant women, or generalized infections in infected neonates (*granulomatosis infantiseptica*) (Fig. 6). If not controlled properly by the immune system, *L. monocytoge-*

nes infection may also cause septicemia. Highly contaminated food products also infect healthy individuals, resulting mainly in gastroenteritis (Aureli et al., 2000; Vazquez-Boland et al., 2001; Wing and Gregory, 2002; Ooi et al., 2005).

DIGESTIVE MANIFESTATIONS Studies reported by the CDC have shown that 11% of the food samples collected in the framework of food monitoring programs were contaminated with *L. monocytogenes* and that *L. monocytogenes* grew from at least one refrigerator sample of 64% of patients with listeriosis (Pinner et al., 1992). For long, this first step of the infectious process—consumption of *L. monocytogenes*-contaminated food—was considered to be almost always clinically silent. However, it was clearly demonstrated that it may lead to the development of a genuine gastroenteritis (with digestive signs such as nausea, aqueous or bloody diarrhea, abdominal pain, and fever) with an attack rate of up to 70%, particularly in cases of high inocula (Dalton et al., 1997; Schlech, 1997; Aureli et al., 2000). Although a number of *L. monocytogenes* associated gastroenteritis outbreaks have been reported, cases of sporadic enteritis appear to be relatively rare (Schlech et al., 2005). The importance of the inoculum size in the onset of these early clinical signs is supported by the results of oral

Table 4. Cost of foodborne infections in the United States in 1992.

Bacteria	Number of cases in the United States in 1992	Global cost ($US)	Cost per patient ($US)
Salmonella	1,920,000	1,388,000,000	723
Campylobacter jejuni	2,100,000	961,500,000	458
Escherichia coli O157H7	14,058	388,000,000	27,600
Listeria monocytogenes	1,550	221,000,000	142,581

For detailed information about the economics of foodborne diseases, see USDA listing of foodborne diseases.
Fig. 6. Successive steps of listeriosis. Organs affected by the infection, symptoms and epithelial barriers crossed by *L. monocytogenes*.

challenges in healthy nonhuman primates, in whom the ingested inoculum had to be higher than 109 organisms to produce a detectable clinical effect (Farber et al., 1991b). Whether these digestive clinical signs mostly account for a toxic effect of *L. monocytogenes* on the intestinal tissue or for the crossing and invasion of the mucosal barrier by *L. monocytogenes* is not known. These digestive manifestations are usually self-limited and resolve spontaneously.

BACTEREMIA In the population at risk for invasive listeriosis, signs accounting for generalized infection most frequently occur after an incubation period that can be very long (10–70 days). Hematogenous seeding of the pathogen resulting in *L. monocytogenes* bacteremia might be responsible for an influenza-like febrile illness, accompanied by myalgias, arthralgias, headache and backache but might also be clinically silent (Goulet and Marchetti, 1996).

PREGNANCY-ASSOCIATED LISTERIOSIS During pregnancy, particularly the third trimester when pregnancy-associated immunosuppression is the most intense, benign common cold symptoms may be due to *L. monocytogenes*-associated bacteremia and should be treated *a priori* as listeriosis because of the seriousness of possible obstetrical and neonatalogical complications. The specific complications of listeriosis during pregnancy lie in the ability of *L. monocytogenes* to cross the maternofetal barrier and result in placental abscesses, chorioamnionitis, and finally infection of the fetus. This infection is responsible for premature labor, stillbirth, abortion, and neonatal infection, with high mortality. Disseminated infection to the fetus is called granulomatosis infantiseptica and is characterized by the widespread presence of microabscesses and granulomas in liver, spleen and skin. The highest concentrations of *L. monocytogenes* being encountered in the gut and in the lung, infection might be amplified through ingestion of contaminated amniotic fluid rather than solely as a consequence of the hematogenous transplacental route (Lorber, 1997; Schlech, 2000). In cases of neonatal contamination during parturition, a primary septicemic syndrome similar to that associated with *Streptococcus agalactiae* infection occurs sometimes with purulent conjunctivitis and disseminated papular rash evocative of neonatal listeriosis and late-onset meningitis. *Listeria monocytogenes* meningitis is one of the three major causes of meningitis in neonates (Lorber, 1997; Dawson et al., 1999; Schlech, 2000; Lecuit and Cossart, 2001a).

INFECTION OF THE CENTRAL NERVOUS SYSTEM *Listeria monocytogenes* has, in addition to its ability to cross initially the intestinal barrier and the maternofetal barrier in pregnant women, the capacity to cross the blood-brain barrier and reach the central nervous system (CNS). Interestingly, it has been proposed, based on animal studies, that infected bone marrow myeloid cells may promote *Listeria* invasion of the CNS (Join-Lambert et al., 2005). *L. monocytogenes* capacity to cause both acute meningitis and parenchymal brain infection differentiates it from other bacteria frequently responsible for meningitis such as *Streptococcus pneumoniae*, *Neisseria meningitidis* and *Haemophilus influenzae*. Among all bacterial meningitides, *L. monocytogenes* meningitis has the highest mortality rate (22%). *L. monocytogenes* meningitis accounts for 11% of all bacterial meningitis and was the second most common cause of meningitis after *Streptococcus pneumoniae* meningitis in patients older than 50 years (Lecuit and Cossart, 2001a). The clinical features of *L. monocytogenes* meningitis differ from those of other bacterial meningitides in that *L. monocytogenes* meningitis may have a subacute course, and be associated with abnormal movements, seizures, and alteration of consciousness. The onset of such signs is evocative of dissemination to the brain parenchyma. Two different types of dissemination to the brain can occur: encephalitis or intraparenchymal brain abscesses. Encephalitis usually involves particularly the rhombencephalon and clinically appears as a meningitic syndrome that is complicated with cranial nerve deficits, a cerebellar syndrome, or central motor and sensitivity deficits. In two-thirds of the cases, blood cultures are positive. Cerebrospinal fluid culture is positive in half of the cases. The onset of rhombencephalitis is not confined to the immunocompromised host and may also be reported in otherwise healthy adults (Armstrong and Fung, 1993). In a small proportion of *L. monocytogenes* CNS infections (10% with half of them in immunocompromized patients), macroscopic brain abscesses are observed. *Listeria monocytogenes* brain abscesses are preferentially located in subcortical areas, thalamus, pons or medulla. These unusual locations are evocative of their listerial origin (Lorber, 1997; Schlech, 2000). Both encephalitis and parenchymal abscesses are associated with high neurological sequelae and mortality rates.

LOCALIZED INFECTIONS Rare cases of *L. monocytogenes* endocarditis have been reported, accounting for less than 10% of all *L. monocytogenes* infections and occurring in patients at risk for endocarditis. Rare localized infections in patients at risk for listeriosis have also been reported and include infections due to direct inoculation (conjunctivitis, skin infection or

lymphadenitis), digestive involvement (peritonitis or cholecystis), or hematogenous seeding (abscesses of liver and spleen, pleuropulmonary infections, joint infection and osteomyelitis, pericarditis, myocarditis, arteritis or endophtalmitis) (Lorber, 1997; Schlech, 2000; Lecuit and Cossart, 2001a).

Genetics of *Listeria*

Genetic Elements of *Listeria*

PHAGES Lysogenic bacteriophages have been isolated from *Listeria* species. They belong to the Siphoviridae and Myroviridae families and contain double-stranded DNA of about 40 kb. They do not appear to be involved in virulence, but some have been used to classify *Listeria* strains by phage typing (Cossart and Mengaud, 1989a; McLauchlin et al., 1996). Phages of *Listeria monocytogenes* are, with a few exceptions, specific with respect to the serogroup of the host cells. The major serogroups (1/2 and 4) can be differentiated on the basis of somatic antigen composition and sugar substitution of cell wall teichoic acids (TAs) (Fiedler and Ruhland, 1987). These carbohydrates also serve as a primary receptor for the serogroup specific phages (Wendlinger et al., 1996). In 2000, the complete nucleotide sequence and structural analysis of the serogroup 1/2-specific bacteriophage A118 were reported (Loessner et al., 2000). The A118 genome is a 40.8-kb, linear, circularly permuted, terminally redundant collection of double-stranded DNA molecules. Site-specific integration of the A118 prophage occurs into a gene homologous to *comK* from *Bacillus subtilis*, resulting probably in the inactivation of this gene. Comparative analysis of the A118 genome structure with other bacteriophages revealed local, but sometimes extensive similarities with a number of phages spanning a broader phylogenetic range of low G+C bacteria, implying relatively recent exchange of genes and genetic modules (Loessner et al., 2000). The genome and the proteome of a serogroup-4-specific phage, PSA, were described in 2003 (Zimmer et al., 2003). PSA is a temperate phage isolated from *L. monocytogenes* strain Scott A, a clinical epidemic strain. The genome of the bacteriophage PSA is 37.6 kb long and contains 57 open-reading frames, which are organized into three major transcriptional units. The PSA integration site is *attB* located at the 3′ end of the single-copy tRNA^{Arg} gene, where phage nucleotides reconstitute its function (Lauer et al., 2002). Bioinformatics revealed only few similarities of PSA with the *Listeria* phage A118. The analyses also revealed the first case of a +1 frameshifting among dsDNA phages, and the utilization of a 3′ pseudoknot to stimulate such an event (Zimmer et al., 2003). On the basis of the analyses of these two bacteriophages and the identification of their respective integration sites, two site-specific integration vectors, pPL1 and pPL2, which utilize the listeriophage U153 integrase, were constructed (Lauer et al., 2002) (Fig. 7). pPL1 integrates in the *comK* attachment site and pPL2 uses the PSA attachment site in the tRNA^{Arg} gene. These plasmids were used in *L. monocytogenes* enabling complementation experiments (Lauer et al., 2002).

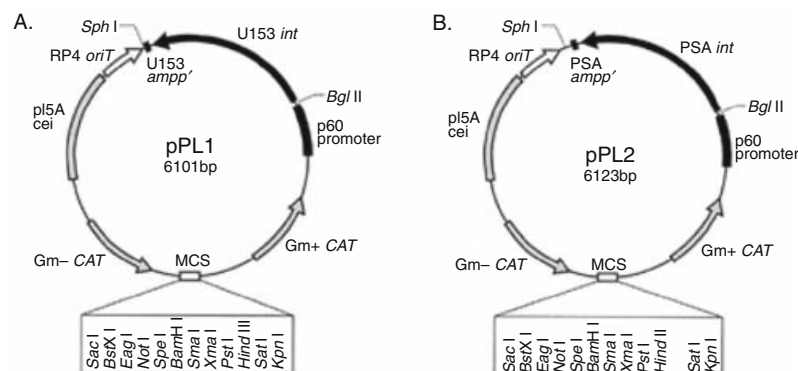
PLASMIDS Many strains of *Listeria* species contain one large cryptic plasmid. Several plasmids of various sizes were detected in *Listeria*, but hybridization and restriction analysis revealed a high degree of homology between them (Kolstad et al., 1991). In certain cases, *L. monocytogenes* plasmids were associated with cadmium resistance (Lebrun et al., 1992) or antibiotic resistance (Charpentier and Courvalin, 1999). Studies on the conjugative abilities of the plasmids associated with antibiotic resistance showed that they were transferable to *Listeria* spp. as well as to other Gram-positive bacteria and suggested that they were probably acquired from the *Enterococci-Streptococci* group (Poyart-Salmeron et al., 1990; Lebrun et al.,


Fig. 7. Maps of the site-specific integration vectors pPL1 and pPL2. Chloramphenicol resistance genes (CAT) and origin of replication in *E. coli* are represented in gray; RP4 origin of transfer is represented in white. The U153 and PSA integrases (U153*int* and PSA*int*) and the p60 promoter of *L. monocytogenes* are represented in black. MCS is the multicloning site. Adapted from Lauer et al. (2002), with permission.

1992; Charpentier and Courvalin, 1999). Plasmid vectors originating from *Bacillus subtilis* or *Escherichia coli* replicate in *Listeria* and thus are used for genetic studies in *L. monocytogenes*, including allelic exchange of chromosomal DNA, cloning, gene expression, or reporter gene fusion (Freitag, 2000).

Transposons Some *L. monocytogenes* strains harbor a natural transposon Tn*5422*, which contains 40-bp inverted repeats, two genes conferring cadmium resistance, and two genes encoding a transposase and a resolvase (Lebrun et al., 1994). *Listeria* can also naturally acquire *Enterococci-Streptococci* transposons from the Tn*1545*-Tn*916* family, conferring on strains tetracycline resistance and other resistance genes (Poyart-Salmeron et al., 1989; Poyart-Salmeron et al., 1992). The conjugative properties of these transposons were widely used for mutagenesis and constituted the first genetic tools to study *L. monocytogenes* virulence and physiology (Gaillard et al., 1986; Kathariou et al., 1987; Portnoy et al., 1988; Cossart et al., 1989b; Marquis et al., 1993). Contrary to conjugative transposons, nonconjugative transposons such as Tn*917* or Tn*917-lac* do not generate multiple insertions and are consequently more powerful tools (Cossart et al., 1989b). More recently, Tn*1545* or Tn*917*–derived tagged transposons were also used for signature-tagged mutagenesis in *L. monocytogenes*, allowing the identification of new virulence genes (Autret et al., 2001; Dramsi et al., 2004; Mandin et al., 2004).

Genetic Techniques and Tools

Genetic techniques used to modify the *Listeria* genome are derived from those (including conjugation of self-conjugative transposons or plasmids, and transformation of plasmids) utilized to modify other Gram-positive bacteria (Cossart and Mengaud, 1989a). Interestingly, *L. monocytogenes* itself has been used as a genetic vehicle to deliver functional genes into eukaryotic cells (Mollenkopf et al., 2001; Grillot-Courvalin et al., 2002; Pilgrim et al., 2003b).

Plasmid Vectors Several shuttle plasmid vectors from *Bacillus subtilis* have been used in *L. monocytogenes*. They contain multicloning sites and genes encoding antibiotic resistance, allowing genetic studies (Freitag, 2000).

Plasmids Preferentially Used for Complementation or Gene Expression Among the broad host range shuttle plasmids replicating in *Escherichia coli* and *L. monocytogenes*, pMK4 and pAM401 are the most extensively used for complementation of mutants obtained by transposon insertion or for expression of gene products via their own promoters (Sullivan et al., 1984; Wirth et al., 1986; Cossart et al., 1989b; Freitag, 2000) (Fig. 8). Similarly, derivatives of the conjugative plasmid, pAT18 (Trieu-Cuot et al., 1991), allowed complementation of deletion mutants (Gaillard et al., 1991; Dramsi et al., 1995) as well as green fluorescent protein (GFP) expression (Fortineau et al., 2000). pBR474 derivatives have also been used to successfully express *L. monocytogenes* proteins. They combine the advantage of an easy selection of recombinants (because of the high natural sensitivity of *Listeria* strains to chloramphenicol) and a high level expression of inserts (because of the presence of a strong promoter) (Lecuit et al., 1997). The recent construction of a plasmid, pLIV1, carrying an isopropyl-β-D-thiogalactoside (IPTG)-inducible SPAC pro-
Fig. 8. Physical map of the pMK4 plasmid. The ampicillin (Ap) and chloramphenicol (Cm) resistance genes allow selection in *E. coli* and *L. monocytogenes*, respectively. From Sullivan et al. (1984), with permission.

moter permitted in vivo studies in which expression of *L. monocytogenes* genes were followed intracellularly (Freitag and Jacobs, 1999; Dancz et al., 2002). The construction of integrative phage-derived plasmids, pPL1 and pPL2, has also allowed complementation of deletion mutants (Fig. 7). Their advantage resides in their ability to integrate at a specific location, which may facilitate fine genetic analysis of mutants or gene transfer in *L. monocytogenes* (Lauer et al., 2002).

Plasmids Preferentially Used for Allelic Exchange Thermosensitive vectors such as pKSV7 (Smith and Youngman, 1992) (Fig. 9) or pAUL-A (Schaferkordt and Chakraborty, 1995) allow allelic exchange, in frame deletion mutagenesis (Brundage et al., 1993; Dramsi et al., 1995; Domann et al., 1997), or site-specific mutagenesis (Boujemaa-Paterski et al., 2001). A novel thermosensitive plasmid, pMAD, harboring the β-galactosidase gene fused to the strong constitutive promoter of *clpB* from *Staphylococcus aureus* (Fig. 10), facilitates the screening and the generation of allelic exchanges (Arnaud et al., 2004).

Transposons Different transposons were used for random mutagenesis in *L. monocytogenes*. Conjugative transposons from the Tn*1545*-Tn*916* family or Tn*917* transposons were initially exploited to generate libraries of mutants, which allowed the characterization of several virulence factors of *L. monocytogenes* (Gaillard et al., 1986; Kathariou et al., 1987; Portnoy et al., 1988;

Cossart et al., 1989b). More recently, tagged Tn*1545* derivatives carried by an integrative vector were utilized for signature-tagged mutagenesis in *L. monocytogenes*, allowing the identification of new virulence genes (Autret et al., 2001). The use of Tn*917* or Tn*917* derivatives (pTV1, pTV32, pTLV1 and pTLV3), carried on vectors with temperature-sensitive origins, facilitated the screening and the generation of large-scale libraries of mutants, in particular those of *L. monocytogenes* virulence genes (Camilli et al.,

1990; Sun et al., 1990; Mengaud et al., 1991b) (Fig. 11). Some of these transposons have also the advantage of allowing the direct cloning of the flanking regions of the transposon insertion site (pTLV1 and pTLV3) or carry a promoterless *lacZ* gene permitting transcriptional gene fusion (pTV32) (Camilli et al., 1990; Francis and Thomas, 1997).

REPORTER GENES Transcriptional fusions to reporter genes, mostly *lacZ*, *lux* or GFP, have been used to monitor *Listeria* gene expression in vitro or intracellularly (Klarsfeld et al., 1994; Bubert et al., 1999; Freitag, 2000). More recently, a transposon carrying a modified version of the *lux* operon fused to promoterless *L. monocytogenes* genes (Francis et al., 2000) has opened a new way to monitor infection using in vivo bioluminescence imaging in mice (Hardy et al., 2002).

CONJUGATION Self-conjugative transposons, plasmids, and phage-derived vectors are used for genetic studies in *Listeria*. Most often, conjugation is performed on filters onto which donor and recipient bacteria are deposited (Cossart and Mengaud, 1989a). pAT18 vectors or derivatives were used for complementation studies of mutants affected in virulence determinants (Gaillard et al., 1991) or to generate *L. monocytogenes* expressing GFP, allowing their detection and tracking in vivo (Fortineau et al., 2000). Conjugative transposons of the Tn*1545*-Tn*916* family transfer from the donor bacteria to the recipient bacteria, where they integrate randomly into the chromosome. This strategy was the first used to

generate a large set of defective mutants (Gaillard et al., 1986; Kathariou et al., 1987; Portnoy et al., 1988; Cossart et al., 1989b; Marquis et al., 1993). Recently, conjugation of listeriophage-derived integrative vectors, pPL1 and pPL2, was successfully exploited for complementation studies of *L. monocytogenes* mutants (Lauer et al., 2002).

TRANSFORMATION Listeriae are not naturally competent, although competence genes have been found in *L. monocytogenes* genome (Glaser et al., 2001). However, transformation with plasmid DNA can be obtained on protoplasts or by electroporation (Vicente et al., 1987; Luchansky et al., 1988). Treatment of bacteria with low concentration of penicillin optimizes the efficiency of electroporation (Park and Stewart, 1990). Genetic studies resulting from *L. monocytogenes* transformation include allelic exchange of chromosomal DNA, complementation of defective genes, and reporter gene fusion (Cossart et al., 1989b; Dramsi et al., 1995; Dubail et al., 2000).

TRANSDUCTION Until recently, transduction was not possible in *L. monocytogenes*. It has now been successfully performed using bacteriophages that grow at 30°C but not at 37°C. Transduction at low multiplicity of infection, at 37°C, and in presence of citrate resulted in elimination of transductant and lysogeny, allowing the isolation of several *L. monocytogenes* transductants of different serotypes, and opening the way to new genetic approaches to modify the *Listeria* genome (Hodgson et al., 2000).

The Cell Biology of *L. monocytogenes* Infection

While our knowledge of the different steps leading to listeriosis remains rather elusive, the cell biology of the infectious process has been widely studied (Figs. 12 and 13). The main feature of *L. monocytogenes* is its capacity to enter into non-phagocytic cells and to survive and multiply in the cytosol of most cell types, including macrophages. Intracytoplasmic bacteria exploit the host cytoskeleton to move intracellularly through an actin-dependent process. (Lecuit and Cossart, 2001; Cossart and Sansonetti, 2004). Interestingly, it was shown that intracytosolic *L. monocytogenes* avoids recognition by the ubiquitin-dependent degradation system, as a possible consequence of its motility (Perrin et al., 2004). *L. monocytogenes* form protrusions that invade adjacent cells, allowing dissemination by direct cell-to-cell spread, without reaching the extracellular milieu, therefore avoiding the extracellular defenses, such as antibodies and complement (Lecuit and Cossart, 2001a; Cossart and Sansonetti, 2004). These features, including the avoidance of lysosomal enzymes and serum components, strongly account for the virulence of *L. monocytogenes*.

Bacterial Internalization

Both in vivo and in cultured cells, *L. monocytogenes* can be phagocytosed by macrophages (Harrington-Fowler et al., 1981; Campbell et al., 1994), neutrophils (Arnold and Konig, 1998), or dendritic cells (Guzman et al., 1995; Kolb-Maurer et al., 2000; Pron et al., 2001). *Listeria monocytogenes* can also induce its own internalization in a wide variety of nonphagocytic cells,

Fig. 14. Electron microscopy of *L. monocytogenes* invading Caco-2 cells. Scanning electron microscopy images of cells infected for 15 min (A) or 30 min (B) by *L. monocytogenes*. including enterocytes (Gaillard et al., 1987; Lecuit et al., 2001b), hepatocytes (Gaillard et al., 1996; Gregory et al., 1996b), fibroblasts (Portnoy et al., 1988), endothelial cells (Drevets et al., 1995; Greiffenberg et al., 1998; Parida et al., 1998) or glial cells of the CNS (Dramsi et al., 1998). Phagocytosis of *L. monocytogenes* in epithelial cells does not produce an extensive remodeling of the cell surface, as seen with *Salmonella-* or *Shigella*-induced ruffling (Swanson and Baer, 1996). Rather it occurs by a zipper-like mechanism, characterized by an intimate bacterium-cell membrane interaction, followed by the progressive invagination of the plasma membrane leading to the bacterial engulfment into the adjacent cell (Mengaud et al., 1996; Figs. 12A and 14). *Listeria* entry into non-phagocytic cells was shown to be dependent on membrane cholesterol (Seveau et al., 2004) and to exploit the clathrin-dependent endocytic cell machinery (Veiga and Cossart, 2005). The entry process is predominantly promoted by two leucine-rich repeat (LRR) proteins, InlA and InlB, expressed at the surface of *L. monocytogenes* and belonging to the internalin (Inl) multigenic family (Gaillard et al., 1991; Dramsi et al., 1995; Braun et al., 1999).

Intracellular Multiplication

After phagocytosis, the vacuole containing *L. monocytogenes* acidifies and, most often, is lysed by the bacterium in less than 30 min (Gaillard et al., 1987; Tilney and Portnoy, 1989; Fig. 12B). In macrophages, escape from the phagosome occurs for approximately 50% of the bacterial population and prevents bacterial destruction by the phagolysosomal components (Tilney and Portnoy, 1989; De Chastellier et al., 1994). It involves principally three bacterial proteins, the pore forming toxin, LLO (Gaillard et al., 1987), PLC-A (Camilli et al., 1993), and the phosphatidylcholine (PC) phospholipase C (PLC-B) (Grundling et al., 2003). Recently, it was suggested that lipoproteins might also participate in the bacterial escape from the phagosome (Reglier-Poupet et al., 2003a). In macrophages, *L. monocytogenes* delays phagosome maturation, which probably accounts for the vacuolar escape (Alvarez-Dominguez, 1997a). *L. monocytogenes* also inhibits the exchange activity of the endosomal trafficking regulator Rab5a, blocking the recruitment of lysosomal proteins to the phagosomes and avoiding the intraphagosomal killing of *L. monocytogenes* (Prada-Delgado et al., 2001; Prada-Delgado et al., 2005). However, acidification of the phagosomes containing *L. monocytogenes* occurs and is required for membrane disruption induced by the bacteria (Beauregard et al., 1997). In non-phagocytic cells, phagosomes containing InlA- or InlB-coated latex beads contain not only endosomal-lysosomal markers but also MSF, which is a member of the septin family involved in membrane fusion events (Pizarro-Cerda et al., 2002).

Escape from phagosomes involves principally three bacterial proteins, the pore forming toxin, LLO (Gaillard et al., 1987), the phosphatidylinositol (PI) phospholipase (PLC-A) (Camilli et al., 1993), and the phosphatidylcholine (PC) phospholipase C (PLC-B) (Grundling et al., 2003). It was suggested that lipoproteins might also participate in the bacterial escape from the phagosome (Reglier-Poupet et al., 2003a).

Once free in the cytosol, *L. monocytogenes* starts multiplying, with an approximate doubling

time of one-hour (Tilney and Portnoy, 1989; Fig. 12C). This is true for most cells studied, but certain listericidal macrophages do not permit intracellular growth, especially when phagocytosis occurs through the C3bi complement receptor CR3 (Drevets et al., 1993). Several genes encoding virulence or metabolic determinants are induced during *L. monocytogenes* intracellular life, including those involved in phagosomal lysis, actin-based motility, and cell-to-cell spreading (Klarsfeld et al., 1994; Freitag et al., 1999; Bubert et al., 2000). Unlike most bacteria, *L. monocytogenes* replicates in the cytosol when it is directly microinjected into cells (Goetz et al., 2001). The cytosol permissiveness for *L. monocytogenes* growth is probably due to its ability to use a variety of cytosolic nutrients, as suggested by the fact that intracellular multiplication of several auxotrophic mutants is not affected (Marquis et al., 1993). Intracytosolic growth of *L. monocytogenes* is dependent on the hexose phosphate transporter *hpt* gene. Expression of *htp* is under the control of the transcriptional activator PrfA (positive regulatory factor A), which regulates most virulence genes (Goetz et al., 2001).

Actin-Based Motility

Upon escape from the phagosome, *L. monocytogenes* gets surrounded by actin filaments and actin binding proteins. The bacteria start moving in the cytosol, where they induce the formation of an actin tail at their rear end, which resembles a comet constantly depolymerizing at its distal end (Tilney and Portnoy, 1989; Cossart and Kocks, 1994; Figs. 12D, 15 and 16). *Listeria monocytogenes* comets are composed of a dense meshwork of cross-linked actin filaments, similar to that induced by *Shigella flexneri* but different from that induced by *Rickettsia conorii*, which are composed of unbranched actin filaments (Gouin et al., 1999, 2005) (Fig. 16). Actin tails are on average 5 µm but can be as long as 40 µm (Tilney and Portnoy, 1989). *Listeria monocytogenes* motility results from the polymerization of cellular actin by the ActA protein expressed at one pole of the bacterial body (Tilney and Portnoy, 1989; Domann et al., 1992; Kocks et al., 1992). The speed of moving bacteria correlates with the length of the comet and is 0.25 µm/s on average. The process of actin polymerization is very dynamic, since the actin tail is constantly polymerizing and depolymerizing, generating the forces to push the bacteria forward (Theriot et al., 1992). Occasionally, propelled bacteria encounter a membrane and form a protrusion (Fig. 12E). When it occurs in the vicinity of an adjacent cell, it allows bacterial dissemination from cell to cell without
Fig. 15. Actin comets formed in PTK2 after infection with *L. monocytogenes*. PTK2 cells are infected with *L. monocytogenes* for 5 h and fixed. Actin is stained with fluorescein-phalloidin (green) and *L. monocytogenes* are labeled with an anti-*L. monocytogenes* antibody detected by a secondary rhodamine-labeled antibody (red). From N. Khelef, unpublished image.
Fig. 16. Electron micrograph of myosin S1 decorated actin comets formed by *L. monocytogenes* (A), *Shigella flexneri* (B) and *Rickettsia conorii* (C) in Hep-2 cells. Adapted from Gouin et al. (1999), with permission.

reaching the extracellular milieu, therefore avoiding the humoral immune response (Tilney and Portnoy, 1989) (Fig. 12F). The actin tail is composed of actin and actin binding proteins. These include the Arp2/3 complex, which is involved in actin nucleation and polymerization (Welch et al., 1997), and VASP, the vasodilator-stimulated phosphoprotein, which directly binds actin (Chakraborty et al., 1995). The actin tail also colocalizes with proteins involved in actin depolymerization, such as cofilin (David et al., 1998; Gouin et al., 1999), or the actin-bundling protein α-actinin (Dabiri et al., 1990) (Fig. 17). The process of *L. monocytogenes* actin based motility involves an Arp2/3-dependent nucleation step and an Arp2/3-independent step,
Fig. 17. Localization of the actin partners during the formation of comets in cells infected by *L. monocytogenes*. Actin is labeled with fluorescein isothiocyanate-phalloidin or bodipy-phallacidin (green). Vasodilator-stimulated phosphoprotein (VASP), α-actinin, ezrin, actin-related protein Arp3, cofilin and capZ (capping protein Z) are labeled using specific antibodies detected with secondary fluorescent antibodies (red). Images are acquired by confocal scanning microscopy. From Gouin et al. (1999), with permission.

which requires fascin, an actin bundling protein (Brieher et al., 2004). In addition, it was shown that PI-3K plays a role in *L. monocytogenes* action motility (Sidhu et al., 2005). Using green fluorescent protein fusions proteins (pleckstrin homology domains of phospholipase C and of Akt, respectively), which bind PI(4,5)P2 and PI(3,4,5)P3 or PI(3,4)P2, to detect these phosphoinositides, it was shown that phosphoinositides are recruited around the moving bacteria and then concentrate at the comet tail, explaining the involvement of PI3-K in *L. monocytogenes* motility (Sidhu et al., 2005). The actin-based motility of *L. monocytogenes* is a good example

of the exploitation of the host cell machinery by pathogenic bacteria to promote their own survival (Cossart, 1997). Moreover, this model was efficiently exploited for a better comprehension of complex cellular processes such as the formation of the leading edge during cell migration (Machesky, 1997; Marx, 2003).

Intercellular Spreading

During intracellular multiplication within primary infected cells, *L. monocytogenes* generates an actin comet tail, which propels the bacteria in random directions and occasionally to the cell
Fig. 18. Plaque formation in 3T3 fibroblasts produced by *L. monocytogenes* infection. Cells were infected with increasing amounts (A1 to A3 and B1 to B3) of *L. monocytogenes* wild-type or *plcB* mutant, or with similar amounts of *L. monocytogenes* wild-type (D), *actA* mutant (C) or *actA* complemented mutant (E). Plaques were visualized by Giemsa staining after 3 days infection. Adapted from Kocks et al. (1992), with permission.

periphery, generating a protrusion, which contains the bacteria. If the moving bacterium encounters the membrane of an adjacent cell, the protrusion invaginates in this cell, generating a double membrane vacuole containing *L. monocytogenes* and part of the actin tail (Fig. 12F and G). The vacuole of the secondarily infected cell is then lysed liberating bacteria into the cytosol and starting a new infectious cycle (Tilney and Portnoy, 1989). Lysis of the double membrane requires both listeriolysin O (LLO) and the phosphatidylcholine phospholipase C (PLC-B), which is matured by the metalloprotease, Mpl (Mengaud et al., 1991c; Domann et al., 1999; Vazquez-Boland et al., 1992; Smith et al., 1995a). The direct cell-to-cell spreading of *L. monocytogenes* can be followed in a plaque formation assay. In this assay, a fibroblast monolayer is infected, covered by an agarose layer containing

gentamicin, which kills extracellular bacteria. After a few hours, plaques corresponding to islets of cells killed by the bacteria can be visualized by Giemsa or crystal violet staining (Kocks et al., 1992; Brouqui et al., 1994; Fig. 18). Their size is proportional to the bacterial ability to infect adjacent cells and disseminate in the monolayer (Havell, 1986). At the molecular level, it was shown that ezrin, a membrane-cytoskeleton linker of the ERM (ezrin-radixin-moesin) family, accumulates at *Listeria* protrusions. Interaction of ERM proteins with membrane components and actin is required for the formation of protrusions and for efficient cell to cell spread (Pust et al., 2005). The *L. monocytogenes* protein ActA plays a key role in cell-to-cell spread since it is required for the efficient actin polymerization responsible for the bacterial motility (Kocks et al., 1992; Cossart and Bierne,

2001). Cell-to-cell spread is an important feature of *L. monocytogenes* pathogenicity since mutants unable to spread from cell to cell is strongly attenuated (Barry et al., 1992). This ability to spread from cell to cell allows bacterial dissemination through an epithelial tissue without reaching the extracellular medium and its antibacterial products including antibodies.

Virulence Factors

Several proteins produced by *L. monocytogenes* are involved in virulence, either in animal or in cellular models. Most of them were identified by transposon mutagenesis in the 1990s (Gaillard et al., 1986; Gaillard et al., 1991; Kathariou et al., 1987; Cossart et al., 1989b; Mengaud et al., 1991b; Kocks et al., 1992). Recently, new techniques, including signature tagged mutagenesis and comparative genomics between pathogenic *L. monocytogenes* and nonpathogenic *L. innocua* isolates, led to the identification of new virulence factors or putative ones (Autret et al., 2001; Glaser et al., 2001; Cabanes et al., 2002, 2004; Dussurget et al., 2002, 2004a; Dramsi et al., 2004; Mandin et al., 2005).

The best characterized virulence factors of *L. monocytogenes* are involved in the four steps of the cell infectious cycle. Entry into epithelial cells is mediated by the internalins InlA and InlB (Gaillard et al., 1991; Dramsi et al., 1995). Lysis of the primary vacuole involves LLO, PLC-A and PLC-B (Gaillard et al., 1987; Camilli et al., 1993; Grundling et al., 2003). Intracellular motility is promoted by the ActA protein (Domann et al., 1992; Kocks et al., 1992). Intercellular spreading involves the ActA protein, LLO, PLC-B, and Mpl, which activates PLC-B (Mengaud et al., 1991c; Kocks et al., 1992; Vazquez-Boland et al., 1992; Smith et al., 1996). Expression of these virulence factors is controlled by the transcriptional regulator PrfA (Kreft and Vazquez-Boland, 2001).

Internalins

Internalins belong to a multigenic family of proteins characterized by a N-terminal domain containing several successive LRR of 22 amino acids. They harbor a signal peptide and are therefore exported at the cell surface (Gaillard et al., 1991; Dramsi et al., 1997; Engelbrecht et al., 1998a; Raffelsbauer et al., 1998). Nine internalins were first identified in the strain EGD (InlA to InlH and InlC2) (Gaillard et al., 1991; Dramsi et al., 1997; Engelbrecht et al., 1998a; Raffelsbauer et al., 1998). The determination of the genome sequence of the strain EGDe then revealed the presence of larger numbers of inter-

nalin or internalin-like genes in the strain EGDe (Cabanes et al., 2002) (Fig. 19). The internalin family can be divided into three classes. The first class comprises internalins containing a LPXTG motif in their C-terminal region (LPXTG proteins), through which they are covalently anchored to the cell wall (Fig. 20). InlA is the best characterized member of this protein family, which contains 18 other members in strain EGDe (Fig. 19A). The second class comprises one internalin in strain EGDe, InlB, which contains a C-terminal region of 80 amino-acid repeats starting with the dipeptide GW modules (Fig. 19B). GW modules mediate a loose association of InlB to the bacterial surface (Fig. 20). A third class is composed of internalins that do not display any surface targeting domain and are therefore secreted in the extracellular medium. InlC is the best characterized member of this family (Fig. 19C). The two first groups of internalins also contain a region of repeated sequences, named B repeats (Vazquez-Boland et al., 2001; Cabanes et al., 2002).

The first internalins to be discovered, InlA and InlB, are the major effectors of *L. monocytogenes* entry into nonphagocytic cells (Gaillard et al., 1991; Dramsi et al., 1995). The functions of the other internalins remain unclear. Single or multiple deletions of internalin genes, including *inlC*, *inlC2-inlD-inlE* (in strain EGD) or *inlG-inlH-inlE* (in strain EGDe), decreased the virulence of *L. monocytogenes* but did not affect entry into epithelial cells or intracellular multiplication (Domann et al., 1996; Dramsi et al., 1997; Raffelsbauer, 1998). This suggests a role for one of these genes in pathogenicity besides invasion. Deletion of the *inlF* gene has no effect on bacterial entry and virulence (Dramsi et al., 1997). A recent study examining double mutants affecting different internalin genes, including, *inlA*, *inlB*, *inlG*, *inlH* and *inlE*, showed that efficient InlA-dependent entry requires the functions of InlC and InlG-InlH-InlE, suggesting a cooperation between the various internalins for efficient cell invasion (Bergmann et al., 2002), as previously shown for InlA and InlB. The presence of multiple internalins suggests that they may also be important for the biology of *L. monocytogenes* besides pathogenesis.

GENETIC ORGANIZATION AND TRANSCRIPTION OF INTERNALIN GENES Internalin genes are dispersed along the chromosome, but some of them are associated in clusters, such as the operon *inlAB* or the clusters *inlG-inlC2-inlD-inlE* or *inlG-inlH-inlE* in *L. monocytogenes* (Vazquez-Boland et al., 2001). Gene rearrangements are suggested by the fact that one internalin locus is different in two other *L. monocytogenes* EGD isolates. Indeed, comparison of the *inlG-inlC2-*

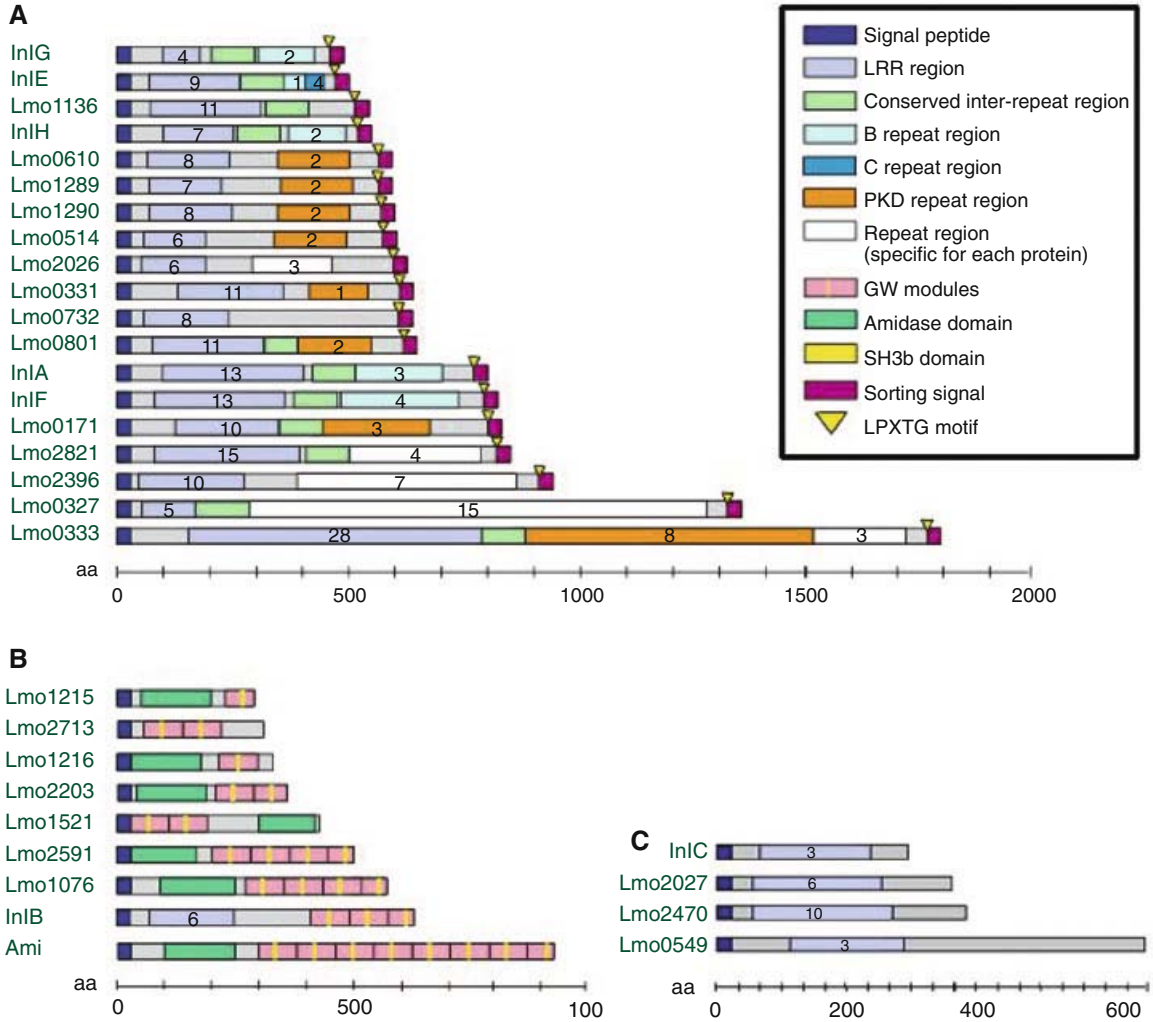

Fig. 19. Alignment of internalin-like LPXTG proteins (A), GW proteins (B), and InlC-like proteins (C). Determined from the annotation of the *L. monocytogenes* genome sequence. The numbers within domains represent the number of repeats. From Cabanes et al. (2002), with permission.
Fig. 20. Association of *L. monocytogenes* surface proteins. Some surface proteins are covalently anchored to the cell wall through a LPXTG motif or loosely attached to the LTAs (lipoteichoic acids) through GW domains. Others are anchored to the cytoplasmic membrane through a hydrophobic tail or a lipid anchor (lipoproteins). From Cabanes et al. (2002), with permission.

Fig. 21. Model for cell wall sorting. The precursor is exported from the cytoplasm via an N-terminal signal sequence (1). The protein is transiently retained in the cytoplasmic membrane by its charged tail and hydrophobic domain (2) allowing recognition and processing of the LPXTG motif by sortase A between the threonine and the glycine residues (3). Sortase A catalyzes the formation of an amide bond between the carboxyl group of threonine and the amino group of the *m*-diaminopimelic acid (DAP) of the cell wall peptidic cross-bridges within a peptidoglycan precursor (4). The precursor is then incorporated into the cell wall by transpeptidation and transglycosylation reactions (5). Adapted from Navarre and Schneewind (1999), with permission.
inlD-inlE locus of strain EGD and *inlG-inlH-inlE* locus of another isolate of strain EGD showed that the *inlH* gene probably resulted from the rearrangement between *inlC2* and *inlD* (Dramsi et al., 1997; Raffelsbauer et al., 1998). The *inlA* and *inlB* genes can be transcribed individually or cotranscribed as an operon (Lingnau et al., 1995; Dramsi et al., 1997). Transcription of the *inlA* gene occurs from three promoters, but only one of them is controlled by the transcriptional activator PrfA, which regulates several virulence factors. This PrfA-dependent promoter also controls *inlB* gene expression (Lingnau et al., 1995; Sheehan et al., 1995; Dramsi et al., 1997). Several internalins (including InlA, InlB, InlC2, InlD and InlE) are also positively regulated by the sigma B factor (Kazmierczak et al., 2003). Transcription of the *inlC* gene is also strongly dependent on the PrfA regulator (Engelbrecht et al., 1996), while the *inlGHE* genes are transcribed individually from a major PrfA-independent promoter (Raffelsbauer et al., 1998).

ANCHORING OF INTERNALINS The various surface proteins of *L. monocytogenes* are associated to the bacterial surface, by interacting with either the plasma membrane, peptidoglycan, or cell wall secondary polymers (Fig. 20). In Gram-positive bacteria, anchoring of LPXTG proteins is mediated by sortase A (SrtA), which catalyzes the covalent linkage of the LPXTG motif to the peptidoglycan, after cleavage of the T-G bond of this motif (Mazmanian et al., 1999; Mazmanian et al., 2001; Navarre and Schneewind, 1999) (Fig. 21). In *L. monocytogenes*, deletion of the SrtA gene abolishes the anchoring of most peptidoglycan associated proteins, including InlA (Bierne et al., 2002b; Garandeau et al., 2002). In the

mouse model of infection, after injection by intravenous or oral routes, the virulence of a SrtA-deficient mutant is attenuated, as compared with the isogenic parental strain and with an InlA-deficient mutant. This suggests that LPXTG proteins other than InlA are required for full virulence in this animal model (Bierne et al., 2002b). InlB is not covalently anchored to the peptidoglycan by a LPXTG motif but instead possesses a 232-amino acid region made of two long tandem repeats starting with the dipeptide GW (Fig. 20). These GW modules are responsible for the loose association of InlB to the bacterial membrane through direct interaction with the lipoteichoic acids (LTAs). In addition, the GW modules of InlB interact with two host cell receptors, the glycosaminoglycans (GAGs) and the complement receptor gC1qR (Braun et al., 1997; Jonquieres et al., 1999; Braun et al., 2000; Marino et al., 2002). InlC and InlC-like proteins lack the LPXTG motif, as well as the B repeat region, and are therefore secreted by *L. monocytogenes* (Engelbrecht et al., 1996).

LRRS MOTIFS OF INTERNALINS The LRRs motifs are often involved in protein-protein interactions. This was demonstrated in the interaction of both InlA and InlB with their specific cellular receptors, respectively the human E-cadherin (Lecuit et al., 1997) and the Met receptor (Shen et al., 2000). In prokaryotes, LRR motifs are present in different virulence factors (Table 5). In eukaryotes, LRR proteins are involved in protein-protein interactions in various cellular processes, including recognition of bacterial pathogens by the Toll-like receptors and Nod proteins (Barton and Medzhitov, 2003; Chamaillard et al., 2003), as well as in plant pathogen defenses (Rathjen and Moffett, 2003).

Table 5. Virulence factors containing LRR motifs.

This similarity could be used as a potential molecular mimicry of the host cell system by the microorganisms.

CELLULAR SPECIFICITY OF INLA AND INLB Both InlA and InlB promote invasion of nonphagocytic cells when coated onto latex beads or expressed by noninvasive bacteria, demonstrating that they are both sufficient for entry (Lecuit et al., 1997; Braun et al., 1998). However, they have different cell specificity, probably due to the presence of their respective receptors on different cell types. InlA mediates entry into cells expressing its receptor, the human E-cadherin, as first shown in vitro for the human enterocyte-like epithelial cell line, Caco-2, and for certain hepatocyte cell lines, such as HepG-2, or placental cells (Dramsi et al., 1995; Mengaud et al., 1996; Lecuit et al., 1997; Lecuit et al., 2004; Bakardjiev et al., 2004). Studies on InlA-dependent entry are now often performed using embryonic fibroblast cells L2071 transfected with the human E-cadherin (Lecuit et al., 2000). In contrast, InlB promotes invasion into several cell types, including certain epithelial cell lines (HeLa, Hep-2 and Vero), hepatocytes (HepG2 and TIB73), brain microvascular endothelial cells (HBMEC), endothelial cells (HUVEC) and fibroblasts (Dramsi et al., 1995; Lingnau et al., 1995; Gregory et al., 1997; Greiffenberg et al., 1998; Parida et al., 1998). Entry through InlA and InlB-dependent pathways were shown to be both dependent on plasma membrane cholesterol, although at different molecular steps (Seveau et al., 2004).

INTERACTION OF INLA WITH ITS RECEPTOR E-CADHERIN AND CONSEQUENCES InlA is the major factor required for *L. monocytogenes* entry into the human enterocyte-like epithelial cell line Caco-2 (Gaillard et al., 1991; Dramsi et al., 1995). When coated onto beads or expressed in noninvasive bacteria, InlA is sufficient to promote invasion of nonphagocytic cells expressing cadherin. Structure function studies showed that the LRRs and the inter-repeat regions of InlA are

sufficient to promote entry into epithelial cells (Lecuit et al., 1997).

Interaction with E-cadherin The receptor for InlA was identified by affinity chromatography as the human E-cadherin, an intercellular adhesion protein, which is highly expressed at the basolateral membrane, in adherens junctions, and possibly on the apical membrane of polarized epithelial cells (Mengaud et al., 1996). E-cadherin is also expressed in hepatocytes, microvascular endothelial cells and choroid plexus cells in the CNS, cytotrophoblastic cells at the placental level, and dendritic cells, suggesting that InlA may target these cells during infection. Interaction of InlA with E-cadherin is the key step in bacterial entry into epithelial cells and in the formation of the phagocytic cup at the entry site. The extracellular domain of E-cadherin interacts with the LRR domain of InlA. *Listeria monocytogenes* recruits α-catenin at its entry site to create a link between E-cadherin and the cytoskeleton through β- and α-catenins (Lecuit et al., 1999; Lecuit et al., 2000) (Fig. 22). Vezatin mediates the bridge between the cadherin-catenins complex and the unconventional myosin VIIa (Kussel-Andermann et al., 2000). Vezatin and myosin VIIa are recruited to the *L. monocytogenes* entry site (Fig. 23) and are involved in the cytoskeleton rearrangements required for efficient InlA-dependent phagocytosis of beads or bacteria (Sousa et al., 2004) (Fig. 24).

Specificity of the InlA-E-cadherin Interaction The InlA-E-cadherin interaction is species specific, since InlA recognizes the human E-cadherin but not the mouse E-cadherin. This specificity is due to a single amino acid, a proline located at position 16 in the binding site of human E-cadherin, which is a glutamic acid residue in the mouse or rat E-cadherins (Lecuit et al., 1999). The completion of the tridimensional structure of the InlA-cadherin complex revealed that the LRR domain of InlA forms a cavity, which is filled by the N-terminal domain of the
Fig. 22. Recruitment of human E-cadherin, β-catenin, α-catenin and actin during InlA-dependent entry. Caco-2 cells infected with *L. innocua* expressing InlA are observed by phase contrast (A, B and C) or by immunofluorescence microscopy after labeling of actin with fluorescent phalloidin (I) or with E- cadherin (D), β-catenin (E and G) and α-catenin (F and H) antibodies detected using secondary fluorescent antibodies. Arrows and arrowheads indicate sites where protein are or are not recruited around bacteria, respectively. Scale bars, 1 μm. From Lecuit et al. (2000), with permission.

human E-cadherin (Fig. 25). Access of E-cadherin to this pocket is blocked when the proline 16 is changed to a glutamic acid (Fig. 26), promoting a steric hindrance, which abolishes the interaction between the two molecules (Schubert et al., 2002).

Role of InlA in Virulence Before the discovery of the species specificity of the E-cadherin-internalin interaction, no role in virulence could be demonstrated for InlA using the mouse model (Gaillard et al., 1996; Gregory et al., 1996a; Pron et al., 1998). The recent demonstration of the specificity of InlA for human E-cadherin explains these data and has allowed further studies. The role of InlA was assessed in a transgenic mouse model, in which the human E-cadherin is expressed at the intestinal level. Infection of these transgenic mice with a wild-type or a Δ*inlA* mutant showed that InlA was important for the crossing of the intestinal bar-

rier (Lecuit et al., 2001b). In guinea pigs, which possess a permissive E-cadherin, infection of the liver, spleen, lymph nodes and small intestine was strongly reduced after oral inoculation with a Δ*inlA* mutant as compared with wild-type *L. monocytogenes* (Lecuit et al., 2001b). These results confirm that, in permissive species, InlA plays a role in the crossing of the intestinal barrier. Recently, a comparative study between *L. monocytogenes* isolates from sporadic or epidemic cases or associated with healthy human carriages revealed that a high proportion of isolates from food expressed a truncated InlA (35%), whereas expression of a truncated internalin is rare in clinical isolates (7%) and notably absent in isolates from maternofetal infections (Jacquet et al., 2004). Interestingly, these isolates with truncated InlA were affected in their invasive ability, as well as in their pathogenic potential in the chick embryo model, suggesting a role for InlA in the establishment of listeriosis
Fig. 23. Recruitment of unconventional myosin VIIa (red) and actin (green) during InlA-dependent entry. Immunofluorescence microscopy images of Caco-2 cells infected with *L. innocua* expressing InlA. Actin is labeled with fluorescent phalloidin. Unconventional myosin VIIa is labeled with specific antibodies detected with secondary fluorescent antibodies. Myosin VIIa is present at the adherens junctions of epithelial cells and is also recruited with actin at the *L. monocytogenes* entry site. Courtesy of Sandra Sousa, unpublished image.

(Jonquieres et al., 1998; Olier et al., 2003). Exchange of the regions encoding InlA between strains expressing full length or truncated InlA confirmed the requirement for InlA in entry (Olier et al., 2005). The role of InlA in *L. monocytogenes* fetoplacental tropism has now been experimentally addressed. The results show that the ability of *L. monocytogenes* to target the placental villi and cross the placental barrier is dependent upon internalin interaction with trophoblast E-cadherin (Lecuit et al., 2004). Thus, *L. monocytogenes* deploys a common strategy to target and cross the intestinal and placental barriers. This raises the possibility that *L. monocytogenes* placental tropism may be a consequence of its evolved mechanism for targeting the intestinal epithelium. Interestingly, the blood-brain barrier is composed of microvascular endothelium and choroid plexus epithelium expressing E-cadherin. Thus, it is tempting to speculate that *L. monocytogenes* targeting to and invasion of the CNS may also be mediated by the interaction between InlA and E-cadherin.

INTERACTIONS OF INLB WITH ITS RECEPTORS The *inlB* gene was first identified as the second gene of the *inlAB* operon involved in *L. monocytogenes* invasion of epithelial cells (Gaillard et al., 1991). InlB has a role in virulence predominantly

for hepatic colonization, as evaluated in the murine model after intravenous infection (Gaillard et al., 1996; Dramsi et al., 1997). InlB is the major protein required for invasion in a variety of cell types in which InlA plays no role, such as hepatocytes, endothelial cells and fibroblasts (Dramsi et al., 1995; Lingnau et al., 1995; Gregory et al., 1997; Greiffenberg et al., 1998; Parida et al., 1998). InlB is sufficient to promote entry of noninvasive bacteria or beads into nonphagocytic cells (Braun et al., 1998). Soluble InlB induces important cytoskeletal rearrangements (Ireton et al., 1999), generating cell membrane ruffling or cell scattering (Shen et al., 2000). These observations support the hypothesis that InlB, when released from the bacterial surface, may facilitate the disruption of epithelial barriers, allowing dissemination of *L. monocytogenes* to deep tissues. Soluble InlB also stimulates the phagocytosis of noninvasive bacteria, probably as a consequence of cell membrane ruffling (Braun et al., 1998).

Structure and Cell Wall Association of InlB As a member of the internalin multigenic family, InlB possesses a LRR domain and a series of repeats starting with a GW dipeptide at its C-terminus. Both the LRR domain and the GW modules are involved in cell receptor recognition (Braun et al., 2000; Shen et al., 2000; Jonquieres et al., 2001; Marino et al., 2002; Machner et al., 2003). The GW modules of InlB mediate its loose association with the bacterial cell wall through interaction with the membrane-associated LTAs (Braun et al., 1997; Jonquieres et al., 2001) (Fig. 27). However, InlB can also be released in the medium and act as a soluble molecule (Jonquieres et al., 1999). Dissection of the tridimensional structure of the different domains of InlB and of the entire molecule revealed that InlB exhibits an elongated and curved structure, facilitating multiple protein-protein interactions. In addition, the X-ray structure revealed that calcium ions are bound to the N-terminal part of InlB (Fig. 28). Interestingly, the 80-amino acid long GW modules of InlB resemble SH3 domains, although the homology appears rather structural than functional (Marino et al., 1999; Marino et al., 2002).

Interactions of InlB with Its Receptors and Consequences InlB interacts with several cellular receptors, gClqR, Met and GAGs, which probably cooperate to promote bacterial uptake, but their respective roles in the signaling responses to InlB remain to be clarified. The first InlB receptor was identified by affinity chromatography as gC1qR (Braun et al., 2000). gC1qR was initially identified as the receptor for C1q, the first component of the complement cascade
Fig. 27. Model illustrating the synergy between the N- and C-terminal domains of InlB to induce efficient signaling. The GW modules of the C-terminal domain are responsible for the loose association of InlB with the bacterial cell wall lipoteichoic acids (LTAs) and bind to the glycosaminoglycans (GAGs). This interaction can detach InlB from the bacterial surface and allow the interaction of its N-terminal leucine-rich repeat (LRRs) domain with Met, the hepatocyte growth factor receptor. From Jonquieres et al. (2001), with permission.
Fig. 28. Three-dimensional structure of InlB. Two different conformers of InlB differing in the path of the B-repeats are represented as ribbons. The red dotted lines represent the B-repeats (not modeled). From Marino et al. (2002), with permission.

(Peerschke et al., 1994). gC1qR is a ubiquitous protein, also called p32. It is present in different subcellular locations and has been involved in various cellular processes, including inflammation and immunity (Ghebrehiwet et al., 2001). InlB-dependent entry is blocked by anti-gC1qR antibodies and by C1q. Moreover, transfection with human gC1qR enhances cell invasion (Braun et al., 2000). These results suggest that gC1qR is an important mediator of bacterial invasion, but since it has neither a transmembrane domain nor a GPI-anchored domain, it was concluded that gC1qR would behave as a co-receptor for a signaling protein. This signaling receptor was later identified as Met, the receptor for the hepatocyte growth factor (HGF). Indeed, Met is a transmembrane protein with a tyrosine kinase activity, which mediates several signaling pathways triggered by InlB. Cells expressing little or no Met are not permissive for InlB-mediated entry and signaling but become permissive when transfected with the human Met receptor (Shen et al., 2000). Both InlB and HGF induce the clathrin-dependent endocytosis and lysoso-mal degradation of Met (Li et al., 2005; Veiga and Cossart, 2005). The Cbl ubiquitin ligase monoubiquitinates Met and is critical for *Listeria* entry into cells (Veiga and Cossart, 2005). InlB also binds directly to cellular GAGs through its GW modules. InlB-dependent entry into epithelial cells is strongly affected by depletion of the cellular plasma membrane GAGs. Finally, heparin, which is a GAG, promotes the detachment of InlB from the bacterial surface and its clustering, suggesting the following model for InlB interaction with its different receptors. Interaction of InlB with GAGs through its GW modules leads to its detachment from the bacterial surface, allowing its clustering at the cellular surface through binding to Met by its LRR domain and favoring the local activation of the signaling pathway downstream of Met (Jonquieres et al., 2001).

Regions of InlB Involved in Receptor Recognition It was shown that the GW modules of InlB interact with gC1qR and GAGs and the LRR domain of InlB binds to Met (Jonquieres

et al., 2001; Marino et al., 2002; Shen et al., 2000). Both regins of InlB, the GW modules and the LRR domain, cooperate for Met activation and InlB-dependent entry (Banerjee et al., 2004).

Species Specificity of InlB As for InlA, InlB was shown to be species specific. It is able to promote entry and ruffling through its Met interaction in humans and mouse cells, but not in guinea pig and rabbit cells, as a problable consequence of Met differences between species (Khelef et al., in press).

InlB-Induced Activation of Phosphoinositide 3-Kinase Cell stimulation with InlB, either soluble or expressed by bacteria, promotes activation of the phosphoinositide 3-kinase (PI3K) (Ireton et al., 1996). This activity strictly depends on the activation of Met. Met recruits and phosphorylates the ubiquitin ligase, Cbl, and the adaptor molecules, Gab1 and Shc, allowing the recruitment of the p85 subunit of type I PI3K to the plasma membrane (Ireton et al., 1999; Shen et al., 2000; Sun et al., 2005). The formation of Gabl-p85 and Gabl-Crk complexes induced by InlB was shown to be important for bacterial entry (Sun et al., 2005). PI3K converts the phosphoinositide PIP2 (phosphatidylinositol 4,5-bisphosphate) into the potent second messenger PIP3 (phosphatidylinositol 3,4,5-trisphosphate), which controls several signaling pathways. In the case of InlB, stimulation of the PI3K through Met activation is critical for phagocytosis, ruffling, and cell scattering, as shown by the inhibitory effects of wortmannin and LY294002, two PI3K inhibitors (Ireton et al., 1996; Ireton et al., 1999; Shen et al., 2000). However, PI3K activation was shown to be dispensable for InlB- or HGF-induced internalization of Met but essential for its lysosomal degradation (Li et al., 2005).

InlB-Induced Phagocytosis Several regulators of actin polymerization and depolymerization are involved in the cytoskeletal rearrangements generated by the interactions of InlB with its receptors have been identified (Bierne and Cossart, 2002a). WASP-related proteins, Abi1, Ena/VASP (Bierne et al., 2005) and the actin nucleator Arp2/3 (Bierne et al., 2001) are recruited to InlB-induced phagocytic cups and membrane ruffles and are required for efficient phagocytosis (Fig. 29). Completion of phagocytosis requires the action of cofilin, which locally depolymerizes actin, allowing the retraction of the cup. Cofilin is recruited to the InlB entry site and accumulates transiently around the nascent phagosome (Fig. 29). The importance of this function was demonstrated by inactivating cofilin, by maintaining it in its inactive form, or by either overexpressing a constitutively activated cofilin

mutant or using a dominant negative mutant of the LIM kinase, which inactivates cofilin. The recruitment of Arp2/3, cofilin, and LIM kinase to the entry site is proposed to occur through the activation of the small GTPase Rac and Cdc42 depending on the cell type (Bierne et al., 2001; Bierne et al., 2005).

InlB-Induced Signaling In addition to its role in phagocytosis, InlB also stimulates other PI3K-dependent pathways, such as the PLC-γ (Bierne et al., 2000), the Ras-Akt-NF-κ B signaling cascade (Mansell et al., 2000; Mansell et al., 2001), and the Ras-MAP kinases pathway (Copp et al., 2003) (Fig. 30). These different pathways have been involved in the regulation of cell survival and anti-apoptosis by growth factors, suggesting that InlB might induce these activities to counteract the deleterious effect of *L. monocytogenes* infection. Since cell membrane ruffling and scattering are also observed after stimulation with InlB and HGF, revealing that InlB behaves as a growth factor (Bierne and Cossart, 2002a).

INTERNALINS IN OTHER *LISTERIA* SPECIES Five internalin genes were first identified in *L. ivanovii* strains, but DNA hybridization experiments showed that internalin-like genes were also present in other *Listeria* species (Gaillard et al., 1991; Dramsi et al., 1997). *Listeria ivanovii* internalins harbor the typical LRR domain. They are small-secreted proteins, while most *L. monocytogenes* internalins are associated with the bacterial cell wall (Engelbrecht et al., 1998b; Vazquez-Boland et al., 2001). Importantly, the two major proteins involved in invasion by the human pathogen *L. monocytogenes*, InlA and InlB, are absent from the animal pathogen *L. ivanovii* suggesting that internalins are critical for Listeriae interactions with their hosts and environment.

Listeriolysin

Listeriolysin O or LLO was the first, and so far the most potent, virulence factor identified in *L. monocytogenes* (Gaillard et al., 1986) (Fig. 4). LLO is a 60-kDa hemolysin belonging to a family of antigenically related cholesterol-dependent pore-forming toxins or cholesterol-dependent cytolysins, which also includes the streptolysin O (SLO) of *Streptococcus pyogenes* and perfringolysin O (PFO) of *Clostridium perfringens* (Gilbert, 2002). Cholesterol-dependent cytolysins are inhibited by oxidation or by thiol-reacting products but reactivated by thiol-reducing compounds (Alouf, 1999). They are characterized by a ECTGLAWEWWR motif, which includes the

(2001), with permission.

unique cysteine residue of the LLO. However, mutation of this residue is not essential for hemolysis, while the last Trp residue of the motif (Trp-432) was shown to play a crucial role for full hemolytic activity and virulence (Michel et al., 1990; Gilbert, 2002).

LLO is encoded by the *hly* gene, which was first identified as a factor absolutely required for virulence by analyzing nonhemolytic mutants obtained by transposon mutagenesis (Gaillard et al., 1986; Kathariou et al., 1987). Virulence of the nonhemolytic mutants is strongly attenuated in the mouse model, with a four log difference in the LD_{50} after intravenous inoculation (Gaillard et al., 1986; Kathariou et al., 1987). Nonhemolytic mutants are also affected in both epithelial and phagocytic cellular models of infection, in which they fail to escape from the phagosomes and to multiply intracellularly (Berche et al., 1988; Kuhn et al., 1988). Genetic analysis of these mutants showed that the LLO defect could be complemented by the reintroduction in trans of the *hly* gene (Cossart et al., 1989b). Similarly, spontane-

ous *hly* revertants recover their hemolytic and pathogenic properties (Gaillard et al., 1986), confirming the central role of LLO in these processes.

LLO is required for escape from both the primary vacuole and of the double membrane-bound phagosomes, cooperating with the PLC-A and PLC-B. It is essential for intracellular multiplication (Gaillard et al., 1987; Bielecki et al., 1990; Gedde et al., 2000). It is proposed that the pore forming ability of LLO mediate the lysis of the vacuoles. In addition, LLO is also responsible for important features of *L. monocytogenes* interactions with the host. They include activation of several signaling pathways (Wadsworth and Goldfine, 1999; Repp et al., 2002; Wadsworth and Goldfine, 2002; Dramsi et al., 2003), production of cytokines (Nishibori et al., 1996), induction of apoptosis of dendritic cells and lymphocytes in vitro (Guzman et al., 1996; Carrero et al., 2004) and of lymphocytes during mice infection (Carrero et al., 2004), and development of a protective immune response against *L. monocytogenes* infection (Berche et al., 1987a;
Fig. 30. The InlB-mediated signaling pathway. InlB buried in the bacterial cell wall may dissociate from the bacterial surface by interacting with glycosaminoglycans (GAGs) and possibly gC1qR (C1q complement component receptor), becoming accessible to bind Met (hepatocyte growth factor receptor). The surface-exposed InlB will trigger entry of the bacteria (1) while a pool of soluble InlB released in the medium will signal independently or as a prelude to bacterial entry (2). Interaction of InlB with Met induces the recruitment of adaptor proteins, the recruitment and activation of the phosphoinositide 3-kinase (PI3K). This triggers actin cytoskeletal rearrangements involving Rho-GTPases and cytoskeletal regulatory proteins and membrane reorganization, which lead to bacterial uptake. Activation of other signaling molecules such as phospholipase C γ (PLC-γ) and the kinase Akt might affect the fate of bacteria and/or cells. From Bierne and Cossart (2002a), with permission.

Pamer, 2004). Antibodies specific for LLO are produced during human listeriosis and their detection is used for diagnosis (Berche et al., 1990). Interestingly, because it can lyse phagosomal membranes, LLO (alone or included in liposomes) has been used as an intracytosolic delivery system for antigens, DNA, or antisense oligodeoxynucleotides. This strategy has been exploited to facilitate research progress in gene therapy, cancer treatment, and vaccination (Lee et al., 1996; Dietrich et al., 2001; Mathew et al., 2003; Provoda et al., 2003).

ROLE OF LISTERIOLYSIN The pathogenic potential of Listeriae has been linked to their ability to induce hemolysis, and therefore to the production of LLO. However, despite its fundamental role in virulence, LLO by itself is not sufficient to confer a pathogenic potential to nonpathogenic Gram-positive bacteria (Portnoy et al., 1992). Moreover, *L. seeligeri*, which has weak

hemolytic activity, is rarely pathogenic for humans, suggesting that hemolysin is not the only factor required for *L. monocytogenes* virulence (Seeliger and Jones, 1986; Hof and Hefner, 1988). Heterologous expression of the *hly* gene in *Bacillus subtilis* enabled this organism to lyse primary phagosomes and to multiply intracellularly, confirming the role of LLO escaping from the primary vacuole (Bielecki et al., 1990). When this experiment was performed with the genes encoding PFO or SLO, it was found that only PFO, and not SLO, promoted phagosomal disruption (Portnoy et al., 1992). This shows that despite the high level of homology of Cholesterol-dependent cytolysins, their ability to disrupt the phagosomal membrane is not conserved. Similarly, expression of ivanolysin, the LLO homologue expressed by *L. ivanovii*, can replace LLO to allow vacuolar escape of *L. monocytogenes*. However, it is not sufficient to confer full virulence in mice, as a •*hly L. monocytogenes* mutant expressing ivanolysin colonizes

efficiently the liver but does not persist in the spleen (Frehel et al., 2003).

MECHANISMS UNDERLYING LISTERIOLYSIN ACTIVITY On the basis of structure-function and biochemical studies, as well as the sequence homology between LLO, PFO and SLO, the mechanism of LLO interaction with membranes is currently thought to be as follows. After an initial step of binding to membrane cholesterol, the toxin monomers diffuse laterally to form ring-shaped oligomers inserted in the membrane bilayer, forming ion-permeable pores (30 nm in diameter) without disrupting the plasma membrane (Vazquez-Boland et al., 2001; Repp et al., 2002) (Fig. 31). Optimal hemolytic activity of LLO is observed at acidic pH, as in the case of phagosomes containing *L. monocytogenes*, supporting the idea that LLO is activated inside the phagosome and inactivated in the cytosol, preventing cellular damage (Geoffroy et al., 1987; De Chastellier and Berche, 1994; Beauregard et al., 1997). Interestingly, LLO is degraded at neutral pH, as a consequence of its denaturation, which results from the unfolding of its transmembrane domain. This process also contributes to the control of LLO activity (Schuerch et al., 2005). Permeabilization of the vacuolar membrane occurs as the pH rises, probably resulting from the equilibration with the cytosol (Beauregard et al., 1997). Experimental evidence for the role of LLO in this process was provided using a mutant of *L. monocytogenes* carrying an IPTG-inducible *hly* gene. IPTG induction was performed when bacteria were in the phagosome, resulting in production of active LLO and disruption of the phagosomal membrane that promoted bacterial release in the cytoplasm (Dancz et al., 2002). Disruption of the primary phagosome and of the double membrane vacuole requires the concomitant effect of the LLO and phospholipase activities (PLC-A and PLC-B, respectively) and leads to disruption of the phagosome, releasing *L. monocytogenes* into the

cytosol (Beauregard et al., 1997; Glomski et al., 2002). Interestingly, LLO is not always essential for phagosome disruption, as in certain cell types (HeLa and HenLe 407), the lysis of the vacuole occurs in absence of LLO and is only mediated by PLC-B (Marquis et al., 1995; Grundling et al., 2003).

Interactions of Listeriolysin with Cholesterol Cholesterol is an important factor for LLO binding to plasma membrane. However, preincubation of LLO with cholesterol inactivates its hemolytic activity without blocking its binding to plasma membranes (Geoffroy et al., 1987; Jacobs et al., 1988; Coconnier et al., 2000). Inhibition appears to occur at the step of toxin oligomerization rather than at the initial step of membrane association (Jacobs et al., 1998; Coconnier et al., 2000). In polarized intestinal cells, LLO is specifically targeted to plasma membrane lipid rafts, probably because of its high affinity for cholesterol, and is internalized through caveolae (Coconnier et al., 2000). In agreement with this, LLO was also shown to aggregate several raft-associated molecules, including a signaling molecule, the Lyn kinase, a process which is proposed to mediate LLO signaling ability. This aggregation is independent of the cytolytic activity of LLO and results from the oligomerization of LLO monomers in the membrane (Gekara et al., 2005). In polarized intestinal cells, internalization of LLO through caveolae leads to stimulation of mucus exocytosis in cultured intestinal mucus secreting cells (Coconnier et al., 2000).

pH Dependence of Listeriolysin As compared with other Cholesterol-dependent cytolysins, the main feature of LLO is its optimal activity at acidic pH (Geoffroy et al., 1987). This property has important consequences since LLO is fully active in acidic vacuoles, which allows escape from the phagosome without destroying the plasma membrane (Beauregard et al., 1997). An elegant study has shown that this property is
Fig. 31. Electron micrograph of red blood cells after treatment with listeriolysin (A) or cholesterol-inactivated listeriolysin (B). Scale bars, 100 nm. From Jacobs et al. (1998), with permission.

important for completion of *L. monocytogenes* infectious cycle. Indeed, intracellular expression of PFO under the control of the *hly* promoter resulted in lysis of the phagosomal membrane but was followed by cell lysis. Mutations in PFO modifying its optimal pH (from neutral to acidic) abolished its cytotoxicity without affecting its ability to disrupt the phagosome (Jones et al., 1996). Conversely, mutations in LLO modifying its pH optimum (from acidic to neutral) conferred a stronger hemolytic activity but also a lower pathogenic potential. Indeed, a *L. monocytogenes* mutant with a LLO active at neutral pH was able to lyse the primary phagosome and to disseminate by cell-to-cell spreading. It was more cytolytic than the wild-type strain. Its LD_{50} was 100-fold higher in the mouse model (Glomski et al., 2002). This attenuated virulence is probably due to the release of cytolytic bacteria into the extracellular milieu and their exposure to antimicrobial defenses. Similarly, mutants of LLO that fail to compartmentalize its activity were more cytotoxic in vitro but less virulent in vivo (Glomski et al., 2003).

PEST-like Motif of Listeriolysin A recent analysis of the N-terminal domain of LLO revealed the presence of a PEST-like sequence, which is involved in targeting proteins to the proteasome dependent degradation pathway. LLO mutants lacking this sequence were cytotoxic and were affected in virulence (Decatur and Portnoy, 2000; Lety et al., 2001). The presence of this PEST-like motif could appear as another strategy to overcome the toxic potential of LLO by targeting the toxin to the degradation pathway when released in the cytosol. However, this theory is challenged by controversial results concerning the role of the PEST motif. One group showed that deletion of the PEST sequence resulted in LLO accumulation in the cytosol without defect in escape from the phagosome (Decatur et al., 2001). Another group showed that mutations in or near the PEST motif of LLO did not promote accumulation of the toxin in the cytosol but decreased LLO ability to disrupt the phagosome. This suggests that the conformation of the domain surrounding the PEST motif, rather than the PEST sequence itself, is important for this activity (Lety et al., 2002; Lety et al., 2003).

LISTERIOLYSIN-INDUCED SIGNALING IN EUKARYOTIC CELLS LLO is a very potent inducer of cell signaling involved in several biological processes, ranging from crucial features of the infectious process to other signals whose roles remain to be clarified. These include stress responses, cell proliferation, secretion of mucus, immunomodulation, or activation of proinflammatory cascades.

Activation of Second Messengers In epithelial and endothelial cells, the pore forming ability of LLO stimulates a transient influx of extracellular calcium, which is mediated by its pore forming ability (Wadsworth et al., 1999; Rose et al., 2001; Repp et al., 2002; Dramsi et al., 2003). The consequences of this activity include modulation of cellular gene expression, signaling, and modulation of *L. monocytogenes* invasion in epithelial cells. LLO modifies the phosphoinotide metabolism and the generation of lipid mediators, such as diacylglycerol, platelet-activating factor, ceramide, and prostaglandins in endothelial cells or platelet-activating factor and leukotrienes in polymorphonuclear leukocytes (PMN) (Sibelius et al., 1996a; Sibelius et al., 1996b; Sibelius et al., 1999; Rose et al., 2001). LLO also induces PMN degranulation characterized by elastase secretion (Sibelius et al., 1999). In macrophages, LLO induces an increase in phosphoinositide hydrolysis, activation of the host PI-PLC, phospholipase D, and protein kinase C (PKC) α and β (Goldfine et al., 2000; Wadsworth and Goldfine, 2002).

Activation of MAP Kinases and Nuclear Factor Cascades LLO induces several well-known signaling cascades, including the Raf-MEK-MAP kinase pathway (Tang et al., 1996; Tang et al., 1998; Weiglein et al., 1997), the NF-κ B and the AP-1 nuclear factor pathways (Kayal et al., 2002; Lievin-Le Moal et al., 2002), as well as calcium- or lipid-dependent signaling pathways. LLO-dependent activation of MAP kinases in HeLa cells concerns Erk2, p38 MAPK, and c-Jun. Hemolytic activity is required for the activation of MAP-kinase activation and for *L. monocytogenes* invasion of HeLa cells (Tang et al., 1998). LLO-induced activation of NF-κ B is implicated in cytokine production, endothelial cell activation, and mucus secretion (Kayal et al., 1999; Rose et al., 2001; Lievin-Le Moal et al., 2002). Activation of NF-κ B involves the classical inactivation of the NF-κ B inhibitor Iκ B kinase in a process that does not involve the interleukin 1 (IL1) signaling pathway (Kayal et al., 2002).

Activation of Mucus Secreting Cells Interestingly, LLO activates the expression of mucin genes and the exocytosis of mucins by polarized intestinal mucus-secreting cells through activation of NF-κ B and AP-1 transcription factors (Lievin-Le Moal et al., 2002). This process is independent of the pore-forming activity of LLO (Coconnier et al., 2000). Importantly, induction of these activities by LLO results in the inhibition of *L. monocytogenes* entry into mucin secreting cells (Lievin-LeMoal et al., 2005).

Activation of Proinflammatory Cytokines
Among the most important signaling activities mediated by LLO is its ability to induce the expression of a wide range of proinflammatory molecules in both macrophages and endothelial cells (Krull et al., 1997; Rose et al., 2001). LLO, either purified or expressed by *L. monocytogenes*, induces the production of interleukins (IL1 and IL12), tumor necrosis factor α (TNFα) and type I interferon β (IFNβ) by macrophages as well as interferon γ (IFNγ) by natural killer (NK) cells (Yoshikawa et al., 1993; Nishibori et al., 1996; Kohda et al., 2002; Nomura et al., 2002; Stockinger et al., 2002). Interestingly, both IL1 and IFNγ production are independent of the hemolytic activity of LLO (Yoshikawa et al., 1993; Nishibori et al., 1996). LLO also activates endothelial cells by stimulating the production of nitic oxide, adhesion molecules (ICAM–1, V-CAM-1 and E-selectin), chemokines and pro-inflammatory cytokines (MCP-1, IL6, IL8 and GM-CSF), probably through NF-κ B activation (Krull et al., 1997; Drevets, 1998; Kayal et al., 1999; Rose et al., 2001). It has been proposed that, in vivo, the production of IFNγ or TNFα mediate the endothelial cell activation, allowing the recruitment of T cells to the site of infection and contributing to the protective acquired immune response against *L. monocytogenes* (Xiong et al., 1994; Vazquez et al., 1995). In the epithelial cell line Caco-2, membrane permeabilization by LLO was shown to trigger expression of the interleukin IL6, in a Ca^{2+} dependent manner (Tsuchiya et al., 2005).

ROLE OF LISTERIOLYSIN IN THE PROTECTIVE IMMUNE RESPONSE LLO is involved in the induction of a protective immune response against *L. monocytogenes* infection in different ways. LLO is a major protective antigen recognized by cytotoxic CD8[+] lymphocytes, in agreement with the cellular immune response characterizing *L. monocytogenes* infection (Berche et al., 1987a; Bouwer et al., 1992; Sirard et al., 1997). Moreover, presentation of major histocompatibility complex (MHC)-I restricted antigens of *L. monocytogenes* and induction of a specific protective immune response result from the release of bacteria inside the cytosol and their intracellular growth. Since LLO mediates this process, it is therefore important for an efficient cellular immune response against *L. monocytogenes* (Darji et al., 1995; Darji et al., 1997). However, LLO also elicits a strong humoral immune response, which, in restricted cases, can be protective against *L. monocytogenes* infection (Berche et al., 1990; Gholizadeh et al., 1996; Grenningloh et al., 1997; Edelson et al., 1999). This has led to the reconsideration of the previous thought that protective immunity against *L.*

monocytogenes infection was only cellular and not humoral. Finally, LLO mediates the delivery of soluble antigen to the MHC-I presentation pathway, which is another way of participating in the induction of specific cellular immunity (Berche et al., 1987b; Brunt et al., 1990; Hitbold et al., 1996; Lee et al., 1996).

Phospholipases and Metalloprotease

Two phospholipases are produced by *L. monocytogenes*, PLC-A or PI-PLC and PLC-B or PC-PLC (Mencikova, 1989; Geoffroy et al., 1991; Leimeister-Wachter et al., 1991; Mengaud et al., 1991a; Mengaud et al., 1991c). Another phospholipase SmcL is produced by *L. ivanovii* (Mencikova, 1989; Gonzalez-Zorn et al., 1999). The three phospholipases have a membrane damaging activity and are involved in bacterial escape from primary and/or secondary phagosomes (Vazquez-Boland et al., 1992; Camilli et al., 1993; Marquis et al., 1995; Gonzalez-Zorn et al., 1999; Grundling et al., 2003). Each of the two *L. monocytogenes* phospholipases is important for virulence since mutants deficient in either PLC-A or PLC-B are attenuated (Camilli et al., 1991; Smith et al., 1995). More importantly, double mutants deficient in both phospholipases are 500 times less virulent than single mutants, emphasizing the importance and the complementarity of these factors in listeriosis (Smith et al., 1995).

PHOSPHOLIPASE PLC-A The phospholipase PLC-A is a 33-kDa secreted protein, whose enzymatic activity is specific for PI (PI-PLC) (Mengaud et al., 1991a). PLC-A is produced by *L. monocytogenes* and *L. ivanovii* and is similar to the PI-PLCs of *Bacillus thuringensis*, *Bacillus cereus* and *Staphylococcus aureus* (Leimeister-Wachter et al., 1991; Mengaud et al., 1991a). PLC-A is encoded by the *plcA* gene, which is upstream of the transcriptional activator gene *prfA* and opposite the *hly* gene encoding listeriolysin O (Leimeister-Wachter et al., 1991; Mengaud et al., 1991a; Mengaud et al., 1991b). During early exponential growth, the *plcA* and *prfA* genes are cotranscribed in a 2.2-kb plcA-prfA transcript. During late exponential growth, *plcA* gene expression is monocistronic. PLC-A expression is dependent on the transcriptional activator PrfA (Mengaud et al., 1991b). The PLC-A crystal structure revealed that it consists of a single $(βα)_8$-barrel domain with its active site at the C-terminal side of the β-barrel (Fig. 32). This structure is highly homologous to the *B. cereus* PI-PLC despite the low sequence homology between the two proteins (Moser et al., 1997).

Enzymatic Activities of PLC-A PLC-A is specifically active on PI but not on PC, phospha-

tidylethanolamine or phosphatidylserine (Goldfine and Knob, 1992). It is active on eukaryotic GPI-anchored proteins including those of *Trypanosoma brucei* membranes, although with a low efficiency as compared with *B. thuringensis* PLC (Goldfine and Knob, 1992; Gandhi et al., 1993). PLC-A has a pI of 9.4 and an optimal pH of 5.5–6.5 in Triton X-100 micelles, in agreement with its intraphagosomal activity (Goldfine and Knob, 1992). Its activity is stimulated by salts, such as $CaCl_2$, $MgCl_2$ or KCl, with no specific dependence on divalent cations, and is not inhibited by EDTA (ethylene diamine tetraacetic acid) (Goldfine and Knob, 1992). Using a fluorigenic substrate analog of PI, the enzymatic properties of the PLC-A were analyzed. It was shown that a short-chain phospholipid (diC(6)PC) activates the enzyme in a process fitting with a two-site model, in which the substrate and the activator bind to different sites interacting with each other (Ryan et al., 2002). Mutations of the two potential active-site histidine residues (H38 and H86) revealed that they are both required for the enzymatic activity and for efficient escape from primary phagosomes (Bannam and Goldfine, 1999). The phospholipase activity of PLC-A can be detected on ALOA chromogenic media, on which *Listeria* expressing PLC-A appear surrounded by a green halo (AES Laboratoires).

Signaling Induced by PLC-A PLC-A mediates endothelial cell activation, characterized by the production of ceramide, activation of NF-κB,

and an increased expression of E-selectin, which stimulates PMN rolling and adhesion (Schwarzer et al., 1998). In endothelial cells and in neutrophils, PLC-A also enhances the phosphoinositide metabolism and the generation of lipid mediators induced by listeriolysin O but is not able to promote this effect by itself when expressed by *L. innocua* (Sibelius et al., 1996a; Sibelius et al., 1999; Goldfine et al., 2000). In macrophages, *L. monocytogenes* infection induces a biphasic activation of NF-κ B. The first transient phase is stimulated by bacterial binding or by purified LTAs. The second persistent phase appears when the bacteria reach the cytosol and correlates with the intracellular expression of PLC-A and PLC-B (Hauf et al., 1997; Goldfine et al., 2000). In addition, PLC-A, along with LLO and PLC-B, is in part responsible for the Ca^{2+} signaling produced by *L. monocytogenes* infection. Indeed, instead of the three calcium spikes produced upon bacterial infection, a ΔplcA mutant generates only a single spike, with no consequence on the efficacy of entry (Wadsworth and Goldfine, 1999).

Role of PLC-A in Infection and Virulence PLC-A has a minor individual role in escape from the primary phagosome but rather acts in synergy with listeriolysin O and PLC-B to fulfill this function, as shown by using simple or double mutants (Camilli et al., 1993; Marquis et al., 1995; Smith et al., 1995). It has no role in cell-to-cell spread, suggesting no role in escape from the double membrane vacuole (Smith et al., 1995). In macrophages, *L. innocua* expressing PLC-A are able to grow inside phagosomes but do not escape from these vacuoles, while *L. innocua* fail to replicate intracellularly, suggesting that PLC-A may possess a secondary function required during intracellular growth (Schwan et al., 1994). *plcA* mutants are slightly less virulent in mice after intravenous inoculation and are defective for liver but not spleen infection (Camilli et al., 1993). However, double ΔplcA-ΔplcB mutants are much less virulent than ΔplcB mutants, confirming the synergy of the two phospholipases in promoting an efficient infection (Smith et al., 1995).

PHOSPHOLIPASE PLC-B The phospholipase PLC-B is a 29-kDa protein with phosphatidylcholine phosphohydrolase activity (PC-PLC, also named lecithinase) produced by *L. monocytogenes* and *L. ivanovii* (Ralovich et al., 1972; Geoffroy et al., 1991; Vazquez-Boland et al., 1992). PLC-B is encoded by the gene *plcB* and is expressed as an inactive precursor. It can be activated by proteolytic cleavage involving the zinc-dependent metalloprotease Mpl, encoded by the gene *mpl*, and also by cellular proteases (Geoffroy et al.,

1991; Raveneau et al., 1992; Marquis et al., 1997). The *plcB* and *mpl* genes are part of an operon, which is controlled by the transcriptional activator PrfA (Mengaud et al., 1991b). The gene *plcB* is homologous to the genes encoding the lecithinases of *Bacillus cereus* and *Clostridium perfringens* (Vazquez-Boland et al., 1992).

Production and Activation of PLC-B In vitro, the PLC-B precursor and its activator Mpl are both secreted and tightly but noncovalently associated with the bacterial cell wall (Snyder and Marquis, 2003). During intracellular growth, translocation of PLC-B is inefficient and it remains at the membrane-cell wall interface. Upon acidification of phagosomes, pools of inactive PLC-B are translocated across the bacterial cell wall (Marquis et al., 1997; Snyder and Marquis, 2003). Activation of PLC-B requires the cleavage of a propeptide. The Mpl-dependent cleavage of PLC-B correlates with its cell wall translocation (Yeung et al., 2005). However, it was shown that PLC-B activation also occurs through a Mpl-independent process mediated by a lysosomal cysteine protease (Marquis et al., 1997).

Enzymatic Activities of PLC-B PLC-B is a zinc-dependent, calcium-independent enzyme, with an optimal activity at pH 5.5–7, in agreement with its role in acidic phagosomes containing *L. monocytogenes* (Geoffroy et al., 1991; Marquis and Hager, 2000). It has a lecithinase activity and is weakly hemolytic (Geoffroy et al., 1991). PLC-B has a broad substrate spectrum and hydrolyzes several lipids, including PC, phosphatidylethanolamine or phosphatidylserine and, to a lesser extent, sphingomyelin and PI (Geoffroy et al., 1991; Goldfine et al., 1993).

Signaling Induced by PLC-B Like PLC-A, PLC-B induces endothelial cell activation characterized by the production of ceramide, activation of NF-κ B, and an increased expression of E-selectin, which stimulates PMN rolling and adhesion, an event which might be important during systemic listeriosis (Schwarzer et al., 1998). Similarly, PLC-B mediates the persistent phase of NF-κ B activation in macrophages when delivered into the cytoplasm during *L. monocytogenes* infection (Hauf et al., 1997). In addition, PLC-B, along with LLO and PLC-B, mediates the Ca^{2+} signaling produced by *L. monocytogenes* infection, which is normally characterized by three calcium spikes. Instead, a Δ*plcB* mutant generates only the first spike resulting in a delayed bacterial internalization rate (Wadsworth and Goldfine, 1999).

Role of PLC-B in Infection and Virulence PLC-B deficient mutants, generated by deletion of the *plcB* or *mpl* gene, are less virulent in mice after intravenous injection (Raveneau et al., 1992). PLC-B also plays a crucial role during murine cerebral listeriosis, since Δ*plcB* mutants are strongly attenuated in the intracranial model of infection (Schluter et al., 1998). PLC-B is involved in the lysis of the double membrane vacuole and therefore in cell-to-cell spreading, as shown with a Δ*plcB* mutant, which forms small plaques on fibroblast cultures (Vazquez-Boland et al., 1992). In certain cell types, such as HenLe 407 and HeLa, but not in macrophages, PLC-B lyses the membrane of primary phagosomes containing *L. monocytogenes* in the absence of listeriolysin (Gaillard et al., 1987; Bielecki et al., 1990; Marquis et al., 1995; Grundling et al., 2003). This suggests that depending on the cell type, PLC-B may act alone or only help LLO to lyse the primary vacuole.

The Sphingomyelinase SmcL of Listeria ivanovii The sphingomyelinase SmcL is produced by the ruminant pathogen *L. ivanovii*. It is encoded by the gene *smcL*, which is present only in *L. ivanovii* but is highly homologous to the sphingomyelinase of *Staphylococcus aureus*, *Bacillus cereus* and *Leptospira interrogans*. SmcL expression is not controlled by the transcriptional regulator PrfA. Its enzymatic activity is responsible for the bizonal hemolysis of *L. ivanovii* and for the CAMP-like reaction, which corresponds to the synergistic hemolysis of *Rhodococcus equi* and *L. ivanovii* (Figs. 4 and 5). SmcL is required for virulence in mice and has a membrane damaging activity, which is required for vacuolar escape of *L. ivanovii* and its intracellular growth (Gonzalez-Zorn et al., 1999). The crystal structure of SmcL has been solved at a 1.9 angstroms resolution, revealing that SmcL adopts a DNasel-like fold and may bind to phospholipids (Openshaw et al., 2005).

ACTA ActA is the protein that mediates actin-based motility (Cossart and Bierne, 2001; Frischknecht and Way, 2001). ActA plays a key role in intracellular movements of *L. monocytogenes*, cell-to-cell spread, and consequently bacterial dissemination into host tissues (Kocks et al., 1992). ActA mutants grow as microcolonies in infected cells (Fig. 33) and their virulence is strongly affected (Domann et al., 1992; Brundage et al., 1993). ActA has also been reported to be required for *L. monocytogenes* entry into epithelial cells (Suarez et al., 2001) and for the recognition of the heparan sulfate receptor at the cell surface (Alvarez-Dominguez et al., 1997).

ActA is a surface protein, which is 610 amino acids long after cleavage of the signal peptide (Domann et al., 1992; Kocks et al., 1992). Note that articles differ in the way they number posi-
Fig. 33. Microcolonies formed by an ActA mutant in Vero cells. After infection for 6 h with *L. monocytogenes* wild-type (A) or ActA mutant (B), Vero cells were fixed. Actin was stained with rhodamine phalloidin (red) or with an anti-*L. monocytogenes* antibody. The ActA mutant, unable to move intracellularly, develops as microcolonies (arrows in B).

tions in the sequence, the codon 1 being either the first codon of the gene (Kocks et al., 1992) or that of the mature protein (Domann et al., 1992).

ActA is anchored to the bacterial membrane by its C-terminal hydrophobic region. Interestingly this region also allows anchoring of heterologous proteins on the mitochondrial surface when these proteins are expressed in eukaryotic cells (Pistor et al., 1994; Friederich et al., 1995). The ActA protein comprises a highly charged N-terminal domain (amino-acids 1–233), a central part made of four proline-rich repeats (amino acids 234–394) and a C-terminal part (amino acids 395–584) (Fig. 34). The ActA protein is a dimer, as originally shown by a yeast two-hybrid approach (Mourrain et al., 1997). In mammalian cells, it is phosphorylated, but the role of this phosphorylation, if any, has not been addressed (Brundage et al., 1993). ActA has been shown to bind phosphoinositides in vitro (Cicchetti et al., 1999; Steffen et al., 2000), but this property has not been investigated in detail. ActA could titrate PIP2, a phosphoinositide that controls the activity of some actin-binding proteins such as capping protein (Steffen et al., 2000).

ActA is polarly distributed on the bacterial surface (Fig. 35). Efforts to understand the origin of this polar distribution have led to the conclusion that the protein accumulates on the two old poles during growth and before division and is not incorporated at the septum during cell division (Kocks et al., 1993). After division, ActA is thus essentially located at one pole and absent from the new pole (Fig. 35). Interestingly, although the polar distribution of ActA, when discovered, appeared quite striking in view of its function in the formation of a polar actin tail (Smith et al., 1995), it has now been shown that many other, but not all, listerial surface proteins display a similar distribution. InlA, for example, is polarly distributed on the bacterial surface (Lebrun et al., 1996), but the amidase Ami does not seem to be polarly distributed (Braun et al., 1997).

ActA is necessary and sufficient to promote actin polymerization. This was first shown by expression of the *actA* gene after transfection in mammalian cells (Pistor et al., 1994). In this experiment, the ActA protein induced actin polymerization and aberrant membrane deformation when targeted to the inner face of the plasma membrane (Friederich et al., 1995). The critical role of ActA was demonstrated by expression of *actA* in the closely related species
Fig. 35. Polarized distribution of ActA at the *L. monocytogenes* surface. Confocal microscopy images of *L. monocytogenes* labeled with ActA specific antibodies detected with fluorescent secondary antibodies large view (A) and close up (C and D). Listeria innocua, a bacterium that is totally non-pathogenic and lives in the environment. *Listeria innocua* expressing *actA* were able to move in cell extracts (Kocks et al., 1995). The final demonstration was achieved by the generation of latex beads coated with ActA, which, like *L. innocua* expressing ActA, were able to move inside cell extracts (Cameron et al., 1999).

Genetic analysis has greatly contributed to the analysis of the ActA protein and its mode of action. It was first shown that the N-terminal part of ActA is the critical part for movement. Bacteria expressing a chimera made of the N-terminal part of ActA and the ω fragment of LacZ can move in cell extracts, demonstrating that the first 233 amino acids are sufficient for movement (Lasa et al., 1995). A series of converging analyses, combined with biochemical approaches, has then demonstrated that this region is structurally and functionally similar to WASP/N-WASP (Wiskott-Aldrich syndrome protein) family proteins of eukaryotic cells and binds actin and Arp2/3 (Lasa et al., 1997; Skoble et al., 2000; Boujemaa-Paterski et al., 2001; Skoble et al., 2001; Auerbuch et al., 2003).

WASP/N-WASP proteins, first identified as mutated proteins in genetic disorders such as the Wiskott-Aldrich syndrome, communicate signals downstream from activated small GTPases to the actin cytoskeleton (Machesky and Insall, 1998). They interact with and activate the multiprotein complex Arp2/3, which is normally inactive in resting cells. Upon activation of cells, e.g. after interaction of a growth factor with its receptor, small GTPases can become activated—they switch from a GDP form to a GTP form—and are thus able to interact directly or indirectly with WASP/N-WASP family proteins, which in turn recruit and activate the Arp2/3 complex. This complex is a seven-protein complex able to stimulate de novo actin nucleation and the generation of a branched meshwork of actin filaments that grow from the sides of existing filaments leading to distinctive 70° branches. The C-terminal part of WASP/N-WASP proteins (called VCA or CA domain) stimulates the actin nucleating activity of Arp2/3 complex. This VCA domain is made of a N-terminal verprolin homology region, which binds actin (V or AB for actin binding in Fig. 34), a hydrophobic region termed the central region C, and a C-terminal segment rich in aspartate and glutamate termed the acidic region A in (Fig. 34). The primary Arp2/3 binding site is the A region, while the C region acting in concert with the V region and a bound actin monomer may drive the conformational changes necessary to stimulate nucleation (Machesky and Insall, 1998). Mutations in the 5′ end of the *actA* gene, in the regions encoding peptidic segments similar to the C and A regions, have definitively established similarities between ActA and other Arp2/3 activators. However, it is important to note the amino-acid stretches that bind Arp2/3 and actin in ActA, in contrast to

WASP/N-WASP family proteins, are not contiguous (Pistor et al., 2000; Skoble et al., 2000; Boujemaa-Paterski et al., 2001). Thus *L. monocytogenes* mimics activation of the Arp2/3 complex by WASP/N-WASP family proteins to achieve motility. However, Arp2/3 activation alone is not sufficient to promote actin-based motility in vitro (Loisel et al., 1999). An actin filament capping protein, either CapZ or gelsolin, and the filament depolymerizing and severing protein ADF/cofilin are also required to achieve motility. CapZ or gelsolin ensure that the actin polymerization driving *Listeria* motility is limited to uncapped filaments closely apposed to the bacterium, whereas ADF/cofilin ensures that actin monomers are made available by depolymerizing actin at the pointed end of the filaments in the tail (Loisel et al., 1999) (Fig. 36).

Another important component of the system, although not absolutely essential, is VASP whose absence decreases the rate of motility ten times (Geese et al., 2002). VASP binds to the proline rich region of ActA. VASP by its property to recruit profilin, which in turn facilitates the formation of ATP-actin from ADP-actin, could provide polymerization competent actin monomers to the ActA-Arp2/3 machinery (Grenklo et al., 2003). Other hypotheses have been proposed (Skoble et al., 2001; Bear et al., 2002; Auerbuch et al., 2003; Samarin et al., 2003). VASP by its ability to compete with capping proteins could stimulate filament elongation (Bear et al., 2002). Alternatively, VASP could increase branch spacing (Samarin et al., 2003).

While ActA is now recognized as a bacterial protein mimicking WASP/N-WASP family proteins, it is important to insist on the very instrumental role that this protein has played in deciphering the role of the Arp2/3 complex in actin-based motility. Indeed, while Arp2/3 complex had been isolated from a profilin-sepharose column in 1994 (Machesky et al., 1994), its role had remained totally mysterious until Mitchison and colleagues fractionated platelet cell extracts and showed that the fraction containing the Arp2/3 complex was able to stimulate an actin cloud around ActA-expressing *Listeria* and that ActA was able to activate Arp2/3 (Welch et al., 1997; Welch et al., 1998). The next important step was the two-hybrid approach used by Machesky and colleagues who showed that one of the subunits of the Arp2/3 complex (used as a bait) binds to WASP/N-WASP family proteins (Machesky and Insall, 1998). Then it was shown that WASP coated beads can move in cell extracts as do *Listeria* bacteria (Yarar et al., 1999). There is no better example of such a large contribution of a bacterial protein to the understanding of a key cell biology process, i.e., actin-based motility. How the force generated by the actin polymerization itself is producing movement is now being studied in detail with ActA-coated objects (Bernheim-Groswasser et al., 2002).

Several other bacteria can use actin to move intracellularly. *Listeria ivanovii* uses a protein similar to ActA (Gouin et al., 1995). Interestingly, *Shigella* uses the outer membrane protein IcsA that recruits N-WASP, which in turn recruits and activates Arp2/3 (Egile et al., 1999). In contrast, *Rickettsia* express an outer membrane protein, RickA, that is similar to WAVE, a member of the WASP/N-WASP family proteins and recruits the Arp2/3 complex (Gouin et al., 2004). However, the actin filaments in the *Rickettsia* tails are totally unbranched raising the possibility that another factor is unbranching the filaments or that the RickA protein itself is also unbranching the filaments. Possibly, other bacteria use variations on the theme to promote their intracellular movements. Recent reports

indicate that *Mycobacterium marinum* (Stamm et al., 2003) and *Burkholderia pseudomallei* (Breitbach et al., 2003) are other examples of intracellular bacteria able to move inside cells.

PEPTIDOGLYCAN AND CELL WALL ASSOCIATED POLYMERS Peptidoglycan (PG) is one of the principal components of the cell wall of Gram-positive bacteria, along with associated polymers, such as the teichoic acids (TAs) and lipoteichoic acids (LTAs) (Fig. 37). It is a thick and rigid structure that covers the plasma membrane, protecting the cytoplasmic content (Merchante et al., 1995). The peptidoglycan and its associated polymers (TAs and LTAs) participate in the maintenance of the bacterial architecture and in anchoring bacterial surface proteins (Jonquieres et al., 1999; Navarre and Schneewind, 1999; Cossart and Jonquieres, 2000). They also possess several biological functions, such as resistance to lysozyme (Kamisango et al., 1982), bacteriophage receptors (Wendlinger et al., 1996), modulator of intracellular signaling in response to infection (Greenberg et al., 1996; Hauf et al., 1997), mitogenicity (Hether et al., 1983b; Paquet et al., 1986), and bacterial adhesion to and invasion of eukaryotic cells (Cowart et al., 1990; Autret et al., 2001).

Composition of the Peptidoglycan The peptidoglycan is a polymer composed of peptides and carbohydrates forming a dense and thick tridimensional network (20–50 nm). The glycans are organized as polymers of *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNAc) residues connected by a β1-4 bond (Fig. 38). The glycan heteropolymers are bound by peptidic bridges through the lactyl group of the MurNAc residue, allowing the constitution of a reticulate network (Archibald et al., 1993). The peptidic polymers are composed of a pentapeptide L-Ala-D-Glu-*meso*-diaminopimelic acid (*m*DAP)-D-Ala-D-Ala and are connected by a direct transpeptidation of the *m*DAP residue with the D-Ala residue of the peptidic bridges (Schleifer and Kandler, 1972; Fiedler et al., 1988; Archibald et al., 1993).

Synthesis and Degradation of the Peptidoglycan Despite its robustness, the peptidoglycan is not an inert structure and the rapid multiplication of *L. monocytogenes* suggests a rapid turnover for
Fig. 37. Model representing a Gram-positive bacterial envelope and its major constituents. Note that a S-layer has not been described in the case of *L. monocytogenes*. From Delcour et al. (1999), with permission.

Fig. 38. Schematic representation of the structure of *L. monocytogenes* peptidoglycan. From Navarre and Schneewind (1999), with permission.

its cell wall components, including the peptidoglycan. The peptidoglycan synthesis occurs as a four-step process. First, there is a sequential ATP-dependent addition of the pentapeptide to the UDP-Mur*N*Ac residues. The newly formed molecule binds the lipid transporter undecaprenol-phosphate to the plasma membrane, which releases the UDP residue. The addition of Glc*N*Ac from the UDP-Glc*N*Ac forms lipid II, which is exported to the external face of the membrane. Finally, the lipid II transfers Glc*N*Ac-Mur*N*Ac-pentapeptide groups to the forming peptidoglycan. The transglycosylation and transpeptidation steps are made by diverse penicillin-binding proteins (Navarre and Schneewind, 1999). The rapid degradation of the peptidoglycan is mediated by autolysins and endolysins, produced by *L. monocytogenes* or its bacteriophages, respectively (Fig. 39). Autolysins and endolysins can cleave different bonds of the peptidoglycan, including the Mur*N*Ac(1-4)Glc*N*Ac (*N*-acetylmuramidases), the Glc*N*Ac(1-4)Mur*N*Ac (*N*-acetylglucosaminidases), the bond between the lactyl group of Mur*N*Ac and the amino group of L -Ala of the branched polypeptide (*N*-acetylmuramoyl-L -alanine amidases), the branched polypeptide at the bond between D-*iso*-Glu and the *m*DAP residues (endopeptidases), and the peptide bridges cross-linking the peptidoglycan between the L-Ala and D-Gln residues (L-alanoyl-D-glutamate peptidases) (Ghuysen et al., 1966; Schleifer and Kandler, 1972).

Composition of the Cell Wall Associated Polymers In *L. monocytogenes*, these polymers comprise TAs and LTAs. In other Gram-positive bacteria, they also include the teichuronic acids and the polysaccharides. These associated polymers are most of the time essential for bacterial growth and viability (Neuhaus and Baddiley, 2003).

TAs are electronegative polymers of ribitol-phosphates covalently bound to the peptidoglycan (Fig. 40). They are substituted by D -Ala residues and diverse sugars, which vary depending on serotypes (Ruhland and Fiedler, 1987; Fiedler et al., 1988; Fischer et al., 1988). LTAs are polymers of glycerophosphate substituted by Ala, galactose, and lipid residues (Fig. 41).

X = –H$_1$ –D-Ala$_1$ –**Galactose**

Recently, the *dlt* operon, which catalyzes the incorporation of D -Ala residues into LTAs, has been characterized. It comprises four genes, *dltA* to *dltD*, with *dltA* supposedly encoding the D-alanine-D-alanyl carrier protein ligase (Abachin et al., 2002). The glycerophosphate chain of LTAs is uncovalently anchored to the outer leaflet of the plasma membrane through a lipid anchor, composed of galactose bound to glycerol and substituted by fatty acids (Gal[α1-2]Glc[α 1-3]diacyl-glycerol) (Hether and Jackson, 1983a; Ruhland and Fiedler, 1987; Greenberg et al., 1996). Contrary to TA, the LTA structure does not vary with serotypes (Fiedler et al., 1988). However, in some *Listeria* strains, LTAs possess an additional phosphatidyl residue, which strengthens their association with the plasma membrane (Fischer et al., 1990). The LTAs are both membrane associated and secreted in the growth medium (Fischer et al., 1988). Their X-ray structure suggests that they adopt a compact organized micellar form with a length of 10–20 nm. Since the cell wall thickness ranges from 20 to 50 nm, some membrane LTAs are probably not exposed to the external medium (Labischinski et al., 1991).

Functions and Biological Activities of the Peptidoglycan and Associated Polymers

Functions Important for Bacterial Structure Probably the most important function of PG and its associated polymers, TAs and LTAs, resides in their participation in the maintenance of the cell wall and bacterial structures. Because of their negative charges, TAs are proposed to participate in the maintenance of a polarized membrane, as well as an electrochemical gradient within the cell wall, which locally concentrates certain ions (Hugues et al., 1973; Jolliffe et al., 1981; Kemper et al., 1993). Similarly, LTAs appear to favor the local concentration of Mg^{2+} ions, which may stabilize the plasma membrane (Roberts et al., 1985). LTAs regulate the activity of autolysins, which are involved in the peptidoglycan degradation required for bacterial growth and division (Fischer et al., 1981).

Role in Anchoring Bacterial Surface Proteins and as Bacteriophage Receptors PG and LTAs are also essential in that they anchor several *L. monocytogenes* surface proteins. Indeed, LPTXG-containing proteins, such as certain internalins, are covalently anchored to the PG allowing their exposure at the bacterial surface. This anchoring is mediated by SrtA (Navarre and Schneewind, 1999). Recently, another sortase, sortase B (SrtB), has been characterized in *L. monocytogenes*. It is required for the anchoring of a small subset of surface anchored proteins and probably recognizes its targets through a NXZTN sorting motif (Bierne et al., 2004). The gene encoding SrtB (*srtB*) is homologous to the *Staphylococcus aureus srtB* gene (Mazmanian et al., 2002). Both are part of an operon that contains at least one of their respective targets and exhibits a Fur (ferric uptake regulator) box, suggesting that their expression might be regulated by iron. One of the substrates of SrtB is the surface protein SvpA (Bierne et al., 2004), which was proposed to act as a virulence factor of *L. monocytogenes* (Borezee et al., 2001). By analogy with the SrtB of *S. aureus*, *L. monocytogenes* SrtB was proposed to be involved in bacterial adaptation to environmental conditions (Mazmanian et al., 2002; Bierne et al., 2004). InlB binds to the LTAs through its GW modules, although this noncovalent linkage appears to be relatively labile since InlB can also be released in the medium (Braun et al., 1998; Jonquieres et al., 1999). Ami, an autolysin involved in bacterial adhesion, also binds to the bacterial surface through its GW modules (Braun et al., 1997). It has also been suggested that the ribose groups of TAs and their associated cations may stabilize external bacterial proteins, protecting them from proteolysis (Chambert and Petit-Glatron, 1999; Hyyrylainen et al., 2000). Finally, the glycan residues of PG and TAs act as receptors for bacteriophages at the surface of *L. monocytogenes* (Wendlinger et al., 1996).

Role in Infection and Immunity In addition to its role in resistance to lysozyme (Kamisango et al., 1982), many reports point to a role of PG in stimulating the immune response. PG was shown early on to activate macrophages and to have

some mitogenic and adjuvant activities (Saiki et al., 1982; Hether et al., 1983b; Paquet et al., 1986). PG induces the production of the migration inhibition factor (Paquet et al., 1986). It enhances the NK activity in vivo and the generation of cell-mediated toxicity against tumor target cells (Saiki et al., 1982; Paquet et al., 1986). PGs were initially proposed to interact with the Toll-like receptor TLR2. However, the use of highly purified fraction of *L. monocytogenes* PGs revealed that they are detected intracellularly by the Nod2 protein and that LTAs contaminants contained in PGs preparations were sensed by TLR2 (Chamaillard et al., 2003; Girardin et al., 2003; Travassos et al., 2004).

TAs share some of the PG properties. They activate macrophages and are mitogenic (Hether et al., 1983b; Paquet et al., 1986). Interestingly, *L. monocytogenes* TAs appear to play a role in adhesion to and entry into epithelial cells. It was recently shown that the glycosylation of TAs favor these processes (Cowart et al., 1990; Autret et al., 2001).

LTAs bind to scavenger receptors on macrophages (Greenberg et al., 1996) and are sensed by TLR2 on epithelial cells (Travassos et al., 2004). In the *L. monocytogenes* strain LO28, a *dltA* mutant affected in the ability to incorporate D-Ala residues into LTAs is less virulent in the mouse model and less adherent to macrophages and epithelial cells (Abachin et al., 2002), suggesting a major role for peptidoglycan in virulence. However, deletion of the *dltA* gene in strain EGD seems to have less effect (Mandin et al., 2005).

AUTOLYSINS AND ENDOLYSINS *Listeria monocytogenes* produces several autolysins that digest its own cell wall peptidoglycan and are therefore listeriolytic. *Listeria monocytogenes* autolysins are proposed to be involved in numerous cellular processes including cell growth and division, septation, cell wall turnover, and peptidoglycan maturation, motility, protein secretion, and virulence (Ward and Williamson, 1984; Blackman et al., 1998; Smith et al., 2000). In addition, certain bacteriophages of *L. monocytogenes* produce endolysins, which are cell wall hydrolases synthesized during late gene expression of the lytic cycle. Endolysins enable the release of progeny virions from infected bacteria through degradation of the bacterial peptidoglycan (Loessner and Scherer, 1995a).

The profile of *L. monocytogenes* peptidoglycan hydrolases comprises multiple bacteriolytic enzymes, as determined by using renaturing SDS gel electrophoresis, with gels containing different bacterial cell wall extracts. Interestingly, the bacteriolytic profiles of different *Listeria* species appear very heterogeneous,
Fig. 42. Alignment of p60-like proteins. Determined from the annotation of the *L. monocytogenes* genome sequence. From Cabanes et al. (2002), with permission.

highlighting the specificity of these enzymes (MacLaughlan and Foster, 1997). Several *L. monocytogenes* autolysins have been more characterized, including p60, p45, Ami, NamA/MurA, and Auto (Wuenscher et al., 1993; Schubert et al., 2000; Carroll et al., 2003; Lenz et al., 2003; Cabanes et al., 2004). In addition, the *L. monocytogenes* genome sequence determination revealed seven other putative autolysins, with amidase or glucosamidase homology domains (Glaser et al., 2001; Cabanes et al., 2004) (Fig. 42).

Autolysin and Endolysin Activities The peptidoglycan of *L. monocytogenes* is composed of a copolymer of GlcNAc alternating with MurNAc, from which are branched polypeptide side chains. Crosslinks result from transpeptidation between the D-alanine of one peptide side chain and the free amino group of the *m*DAP of another (Dhar et al., 2000). Autolysins and endolysins are classified according to their hydrolytic specificity towards the peptidoglycan bonds (Fig. 39). *N*-acetylmuramidases and *N*-acetylglucosaminidases cleave the MurNAc(1-4)GlcNAc or the GlcNAc(1-4)MurNAc bonds, respectively. *N*-acetylmuramoyl-L-alanine amidases cleave the bond between the lactyl group of MurNAc and the amino group of L-Ala of the branched polypeptide. Endopeptidases directly cleave the branched polypeptide at the bond between D-*i*Glu (isoglutamine) and the *m*DAP residues (Ghuysen et al., 1966). L-Alanoyl-D-glutamate peptidases cleave the peptide bridges crosslinking the peptidoglycan between the L-Ala and D-Gln residues (Schleifer and Kandler, 1972).

Autolysins

p60 The autolysin p60 is encoded by the *iap* (invasion-associated protein) gene, which is transcribed independently of the transcriptional activator PrfA and whose expression is controlled at the post-transcriptional level (Kohler et al., 1991; Bubert et al., 1997; Bubert et al., 1999). It is both secreted and associated with the bacterial cell

wall (Kuhn and Goebel, 1989; Ruhland et al., 1993; Wuenscher et al., 1993). Secretion is mediated by the recently identified auxiliary secretion system SecA2, which mediates the secretion of at least seventeen secreted and surface proteins of *L. monocytogenes* (Lenz et al., 2003). p60 is expressed by all *Listeria* species with specific protein sequences for each species (Bubert et al., 1992b; Bubert et al., 1994; Gutekunst et al., 1992a). This finding can be exploited as a way to identify *Listeria* species (Bubert et al., 1992a; Bubert et al., 1994). On the basis of its similarity to LytF from *Bacillus subtilis*, p60 is proposed to have a D-*i*Glu-*m*DAP endopeptidase activity (Lenz et al., 2003).

In agreement with its peptidoglycan activity, p60 has been shown to be important for septum formation during bacterial division and therefore for bacterial viability (Wuenscher et al., 1993). For a long time, Δ*iap* mutants could not been obtained, suggesting that the protein was essential for bacterial viability. Therefore, the role of p60 was first evaluated in rough mutants expressing lower levels of p60 and forming long filamentous structures composed of bacterial chains (Kuhn and Goebel, 1989). The rough mutants are less virulent and enter less efficiently in certain eukaryotic cells, suggesting a role for p60 in bacterial invasion (Kuhn and Goebel, 1989; Gutekunst et al., 1992b; Hess et al., 1995). A viable Δ*iap* mutant was recently obtained, allowing more precise studies of the role of p60 in virulence. As for rough mutants, they also had a defect in septum formation and in virulence after intravenous infection of mice. In addition, the Δ*iap* mutant is impaired in bacterial movement and spreading from cell to cell because of an improper localization of the ActA at the surface *L. monocytogenes*. This abolishes the ability of ActA to polarly polymerize actin and to generate normal comet tails (Lenz et al., 2003; Pilgrim et al., 2003a).

p60 plays an important role in the immune response towards *L. monocytogenes* infection. Antibodies specific for p60 can act as opsonins and may play a role in preventing systemic infections in immunocompetent individuals (Kolb-Maurer et al., 2001). Moreover, p60 is a major protective antigen that induces both T-CD8 and Th1 protective immune responses, highlighting that both cellular and humoral immunity are important to fight *L. monocytogenes* infection (Harty and Pamer, 1995; Bouwer and Hinrichs, 1996; Geginat et al., 1998; Geginat et al., 1999).

p45 The autolysin p45, encoded by the *spl* gene, was identified using a monoclonal antibody raised in mice against heat-killed bacteria. It is a 45-kDa protein with peptidoglycan lytic activity against *L. monocytogenes*. p45 is homologous to the autolysin p60 of *L. monocytogenes* and to Gram-positive secreted proteins of unknown activity, P54 of *Enterococcus faecium*, and Usp45 of *Lactococcus lactis*. p45-like proteins are present in all *Listeria* species, except *L. grayi*. p45 is found both as a secreted protein, as expected from the presence of a 27-amino acid signal peptide, and associated with the cell wall, in a strong but noncovalent fashion, as determined by SDS extraction. This behavior is reminiscent of p60 and of the two main effectors of *L. monocytogenes* invasion, InlA and InlB (Schubert et al., 2000).

Ami The autolysin Ami is a 102-kDa protein produced by *L. monocytogenes*. It is probably an amidase according to the sequence homology of its catalytic domain with other amidase domains (Braun et al., 1997). It is associated to the bacterial surface by a domain containing a series of GW modules, similar to those of one of the major proteins required for *L. monocytogenes* invasion, InlB (Braun et al., 1997; Jonquieres et al., 1999) (Fig. 19B). There is increasing evidence that certain autolysins, like Ami, may act as complementary adhesins during infection. Indeed, inactivation of Ami in mutants devoid of either one or two of the main effectors of *L. monocytogenes* invasion, InlA and/or InlB, resulted in a strong reduction of adhesion to hepatocytes, HepG2, and to the enterocyte-like cell line, Caco-2. On the contrary, inactivation of Ami alone affected only slightly the adhesion to hepatocytes, HepG2 (Milohanic et al., 2001). As for InlB, the cell wall-anchoring (CWA) domain containing the GW modules appears to promote Ami adhesion to cells (Heilmann et al., 1997; Hell et al., 1998; Milohanic et al., 2001). As a probable consequence of its role in adhesion, a mutant with inactivated Ami is slightly attenuated in the liver of mice infected intravenously, indicating a role for Ami in *L. monocytogenes* virulence (Milohanic et al., 2001). Ami from two different epidemic serovars (1/2a and 4b) were compared and their CWA domains were shown to be variable, as compared with the rest of the molecule. The purified CWA domain of Ami from serovar 4b binds less efficiently to Hep-G2 cells as compared with that of serovar 1/2a (Milohanic et al., 2004).

NamA/MurA Two recent concomitant studies identified a new peptidoglycan-hydrolyzing enzyme in *L. monocytogenes*, which was named by the authors "NamA" for *N*-acetylmuramidase or "MurA" for muramidase (Carroll et al., 2003; Lenz et al., 2003). Comparative analysis of biochemical and genetic properties of the two molecules revealed NamA is the same protein as MurA (D. Cabanes, personal communication).

Characterization of the auxiliary protein secretion system, SecA2, revealed that the secretion of several proteins was dependent on this system, including the autolysin p60 and a protein homologous to NamA (Lenz et al., 2003). In parallel, a cell wall hydrolase (MurA) encoded by the *murA* gene was detected by a *L. monocytogenes*-specific monoclonal antibody (EM-7G1), which also recognizes the autolysin p60 (Carroll et al., 2003).

MurA is a major cell surface protein of *L. monocytogenes*. The C-terminal domain of MurA contains four copies of a KM repeat motif, which is also present in p60 and is proposed to be involved in cell wall anchoring. MurA shares homologies with the autolysin p60 and with muramidases. In agreement with this, MurA exhibits a peptidoglycan lytic activity specific for *Micrococcus lysodeikticus*. A deletion mutant of *mur*A lacking the cell wall hydrolase activity is affected in *L. monocytogenes* autolysis and grows as long chains during exponential growth, as a consequence of a septation defect (Carroll et al., 2003). The role of MurA in cell infection and in virulence was not tested in this study, but the study of NamA revealed a moderate role in *L. monocytogenes* persistence in mouse organs (Lenz et al., 2003).

Auto Recently, a novel autolysin encoding gene, *aut*, was identified. It is the only autolysin gene that is absent from the nonpathogenic bacteria *L. innocua*. The *aut* gene is expressed independently of the virulence gene regulator PrfA and encodes a surface protein, Auto, with an autolytic activity, as expected from the presence of a domain harboring homologies with autolysin encoding genes, especially *N*-acetylglucosaminidases. The protein Auto possesses a C-terminal cell wall-anchoring domain made up of four GW modules, similar to those observed in the other autolysin Ami and in InlB, one of the major invasion proteins of *L. monocytogenes*. The morphology of a Δ*aut* deletion mutant was similar to those of the wild-type, with no defect in septation and cell division, suggesting no role for Auto in these functions (Cabanes et al., 2004).

Auto is required for entry of *L. monocytogenes* into different nonphagocytic eukaryotic cell lines but is not required for efficient adhesion, formation of comet tails, or cell-to-cell spreading. A Δ*aut* deletion mutant has a reduced virulence following intravenous inoculation of mice and oral infection of guinea pigs, which correlates with its low invasiveness. However, the autolytic activity of Auto by itself, rather than an invasive ability, might be critical for virulence. Indeed, Auto may control the general surface architecture exposed to the host by *L. monocytogenes* and/or the composition of the surface

products released by the bacteria, highlighting the possible direct role of autolysins in pathogenicity (Cabanes et al., 2004).

FlaA Listeria monocytogenes can move by means of flagella-based motility. The flagellum is composed of a single protein, FlaA (Dons et al., 1992). FlaA also facilitates initial contact with epithelial cells and contributes to effective invasion in vitro (Dons et al., 2004). It was shown that the purified FlaA protein functions as a peptidoglycan hydrolase (Popowska and Markiewicz, 2004). The flagellar protein FlgJ of *Salmonella*, was previously shown to have peptidoglycan hydrolyzing activity, locally digesting the murein sacculus to permit assembly of the rod structure of the flagellum (Nambu et al., 1999). FlaA of *L. monocytogenes* is the first gram-positive flagellar protein demonstrated to have a peptidoglycan hydrolyzing activity.

Endolysins Three endolysins, Ply118, Ply500 and Ply511, produced respectively by the bacteriophages A118, A500 and A511, have been characterized in *L. monocytogenes*. They induce rapid lysis of *Listeria* strains from all species but not of other bacteria (Loessner and Scherer, 1995a). Ply511 is an *N*-acetylmuramoyl-L-alanine amidase, while Ply118 and Ply500 are L-alanoyl-D-glutamate peptidases (Schleifer and Kandler, 1972). A cell wall binding site has been characterized in the C-terminal domains of Ply118 and Ply500 as being sufficient to direct the enzymes to their substrates (Loessner et al., 2002). *Listeria innocua* carries a cryptic phage 2438, which produces the Cpl2438 enzyme highly similar to Ply500 (Zink et al., 1995). A gene homologous to the Ply118 endolysin was detected in the genome sequence of the cryptic phage of *L. monocytogenes* strain EGDe (Glaser et al., 2001). The specificity of these endolysins for *Listeria* cells was exploited in different applications, such as rapid in vitro lysis of *Listeria* cells (Loessner et al., 1995b; Dhar et al., 2000), or programmed self-destruction of intracellular *Listeria* cells within the cytosol of macrophages (Dietrich et al., 1998).

OTHER FACTORS INVOLVED IN *L. MONOCYTOGENES* INFECTION Several factors have been involved in the *L. monocytogenes* infection process either at the level of adhesion, entry, escape from the phagosome, or intracellular multiplication, or at an unknown step.

LAP LAP (*Listeria* adhesion protein) is a 104-kDa protein present both in the cytoplasm and secreted by *L. monocytogenes*. LAP is expressed by all *Listeria* spp. except by *L. grayi* (Pandiripally et al., 1999). LAP mediates *L.*

monocytogenes binding to intestinal epithelial cells but not to nonintestinal epithelial cells, such as liver, kidney or skin cells. Interestingly, the specificity of LAP is even more restricted since it is required for full adhesion to intestinal epithelial cells lines from the ileum-cecum and colon but not from the duodenum or jejunum. These results suggest that LAP may play a role during the intestinal phase of the infection (Jaradat et al., 2003). The heat shock protein Hsp60 has been reported to act as a cellular receptor for LAP on the intestinal cell line Caco-2 (Wampler et al., 2004).

SvpA SvpA (surface virulence-associated protein) is a 64-kDa protein both anchored at the bacterial surface by SrtB and secreted in the extracellular medium (Borezee et al., 2001; Bierne et al., 2004). Its expression is not controlled by PrfA, the transcriptional activator of most virulence factors. A mutant deficient in SvpA was reported to be less virulent in the mouse model after intravenous infection (Borezee et al., 2001). However, the relevance of this result is unclear since virulence of a mutant deficient in SrtB, in which SvpA is no longer exposed at the surface, is not affected (Bierne et al., 2004). The growth defect of the *svpA* mutant may explain its virulence attenuation (H. Bierne and P. Cossart, unpublished results). Another possibility is that the expression of SvpA at the bacterial surface is not important for its role in virulence.

LpeA LpeA (lipoprotein promoting entry) is a 35-kDa protein identified by in silico analysis of the *L. monocytogenes* genome sequence. Despite its homology with PsaA, a *Streptococcus pneumoniae* adhesin, LpeA is not involved in adhesion of *L. monocytogenes*. Instead, it is required for entry into the intestinal and hepatic cell lines. Interestingly, a LpeA-deficient mutant survive longer in macrophages than wild-type bacteria and is slightly more virulent for mice (Reglier-Poupet et al., 2003b).

FbpA FbpA (fibronectin binding protein) is a 60-kDa protein identified by signature-tagged mutagenesis. It is required for efficient liver colonization of mice inoculated intravenously and for intestinal and liver colonization after oral infection of transgenic mice expressing human E-cadherin. FbpA binds to immobilized human fibronectin and increases adherence of wild-type *L. monocytogenes* to HEp-2 cells in the presence of exogenous fibronectin. Despite the lack of conventional secretion/anchoring signals, FbpA is detected on the bacterial surface. Strikingly, FbpA expression affects the secretion of two virulence factors, LLO and InlB, and coimmuno-precipitates with these two proteins. Thus, FbpA, in addition to being a fibronectin-binding protein, may behave as a chaperone or an escort protein for two important virulence factors and appears to be a novel multifunctional virulence factor of *L. monocytogenes* (Dramsi et al., 2004).

Stp Analysis of the *L. monocytogenes* EGDe genome sequence revealed the presence of putative eukaryotic-like phosphatases. Accordingly, the *stp* gene encodes a membrane associated Mn^{2+}-dependent serine-threonine phosphatase, required for *L. monocytogenes* virulence. Using a phosphoproteomic approach, the translation elongation factor EF-Tu was identified as the first target of Stp (Archambaud et al., 2004).

Vip Vip is a novel virulence factor of *L. monocytogenes*, identified by comparative genomics. Vip is a LPXTG surface protein anchored to the cell wall by sortase A. It is positively regulated by PrfA, the transcriptional activator of the major *L. monocytogenes* virulence factors. Vip is implicated in entry into some mammalian cells. Gp96, an endoplasmic reticulum resident chaperone protein (Li et al., 2002), which is also localized at the cell surface, was identified as a cellular receptor for Vip (Cabanes et al., 2005). The Vip-Gp96 interaction is critical for bacterial entry into cells. In murine models, Vip plays a role in *L. monocytogenes* virulence at the intestinal level and at late stages of the infectious process. Vip appears as a new virulence factor exploiting Gp96 as a receptor for cell invasion and/or signaling events that may interfere with the host immune response in the course of *Listeria* infection (Cabanes et al., 2005).

RESISTANCE TO STRESS *Listeria monocytogenes* is ubiquitous in nature and can infect many animal species. The pathogenic bacterium is adapted to survive and/or multiply under a wide variety of harsh environmental conditions, outside as well as inside the host. In food-processing plants, food products, and nature, *L. monocytogenes* has to contend with suboptimal growth conditions, such as refrigeration temperatures, heat, high osmolarity, high pH, and low water activity. Survival has been reported from −0.4°C to 45°C (Farber and Peterkin, 1991a), at salt concentrations up to 10% (McClure et al., 1991), alkaline conditions up to pH 9 (Cheroutre-Vialette et al., 1998). In the human host, *L. monocytogenes* encounters stressors such as lysozyme in saliva, blood, neutrophils and monocytes, reactive oxygen and nitrogen species in the host cell phagosomes, bile salts, digestive enzymes in the small intestine, and stressful microenvironments (such as nutrient deprivation in the host cell cytoplasm, acidic

pH of the stomach, and low oxygen tension and high osmolarity in the intestine). *Listeria monocytogenes* survives and/or grows at a pH as low as 4, even 3 after acid adaptation (Cotter and Hill, 2003) and in the presence of a high concentration of bile (Begley et al., 2002). *Listeria monocytogenes* has evolved a series of adaptive responses to cope with this large variety of stresses.

The first step in stress survival strategies is the sensing of stress conditions and/or stressors and the transduction of a signal leading to an appropriate response (Fig. 43). Two-component signal transduction systems are used for stress sensing by many bacteria, including *L. monocytogenes*. Deletion of *L. monocytogenes* LO28 *lisK*, the gene encoding the membrane-associated sensor histidine kinase of the LisRK two-component system, affects acid and ethanol tolerance and attenuates virulence in mice (Cotter et al., 1999). Using a deletion mutant of the response regulator gene *lisR*, Kallipolitis et al. confirmed the role of the LisRK system in virulence, acid and ethanol tolerance. LisR was also shown to be involved in response to oxidative stress, as growth of the *lisR* mutant was strongly inhibited by 0.025% hydrogen peroxide. Two other response regulators contribute to pathogenicity and stress response in *L. monocytogenes* LO28 strain, a regulator showing 52% identity with the potassium uptake protein KdpE of *Clostridium acetobutylicum* and a regulator showing 43% identity with the *Enterococcus faecium* VanR protein involved in vancomycin resistance (Kallipolitis and Ingmer, 2001).

Many stress response mediators have been identified in *L. monocytogenes*, including chaperones that maintain protein integrity under damaging conditions and proteases that degrade damaged proteins. The DnaK heat shock chaperone is required for survival of *L. monocytogenes* under high temperatures and acidic conditions, as well as for phagocytosis by macrophages (Hanawa et al., 1995; Hanawa et al., 1999). The major heat shock chaperones GroES and GroEL are induced at high temperature (Hanawa et al., 1995; Gahan et al., 2001), at low pH and during infection of J774 cells (Gahan et al., 2001). The ClpC stress protein, an ATPase that belongs to the HSP-100/Clp family, is required for survival under iron deprivation, high temperature or high osmolarity, in bone marrow macrophages and in organs of mice infected by *L. monocytogenes* (Rouquette et al., 1996; Rouquette et al., 1998). Two other proteases have been reported to be involved in stress response and virulence, namely the HSP-100 family member ClpE (Nair et al., 1999) and the serine protease ClpP (Gaillot et al., 2000). Several other proteins involved in specific stress responses have been characterized in *L. monocytogenes*. The major cold shock protein of *L. monocytogenes* is the nonheme ferritin-like protein Flp, also designated Fri (Hebraud and Guzzo, 2000). Fri promotes adaptation to nutritional and thermal shifts, provides protection against reactive oxygen species *in vitro* and is required for full virulence of *L. monocytogenes* (Olsen et al., 2005; Dussurget et al., 2005). The glutamate decarboxylase system plays an important role in survival at low pH found in food (Cotter et al., 2001b) and in gastric fluid (Cotter et al., 2001a). The F_0F_1-ATPase could also contribute to acid tolerance of *L. monocytogenes*
Fig. 43. Schematic representation of the stress resistance process in *L. monocytogenes*. From Hill et al. (2002), with permission.

(Cotter et al., 2000). Adaptation to osmotic stress depends on the intracellular accumulation of osmolytes, e.g., betaine, carnitine and proline (Ko et al., 1994; Fraser et al., 2000). Uptake systems include the Na$^+$-dependent betaine porter I BetL (Sleator et al., 1999), the ATP-dependent betaine porter II GbuABC (Ko and Smith, 1999), the carnitine uptake systems OpuC (Fraser et al., 2000; Sleator et al., 2001a; Sleator et al., 2003; Wemekamp-Kamphuis et al., 2002), and the oligopeptide permease OppA (Borezee et al., 2000). In addition, one osmolyte synthesis system has been described in *L. monocytogenes*, that of proline. Mutation of the *proAB* operon leads to an increased sensitivity to salt (Sleator et al., 2001a). Several of these systems have been shown to play a role in the virulence potential of *L. monocytogenes*, e.g., OpuC (Sleator et al., 2001b) and OppA (Borezee et al., 2000). Bile tolerance of *L. monocytogenes* involves the bile salt hydrolase Bsh, an enzyme that deconjugates bile salts and that is required for both intestinal and hepatic phases of listeriosis (Dussurget et al., 2002; Begley et al., 2005). The transporter BtlA (Begley et al., 2003) and other systems (such as the putative transporter of the glutamate decarboxylase GadE, the penicillin V amidase Pva, the bile tolerance protein BtlB, the bile exclusion system BilE and the zinc uptake regulator ZurR) contribute to tolerance to bile or various other stresses, e.g., low pH, salt, ethanol, detergents and antibiotics (Begley et al., 2002; Sleator et al., 2005a; Begley et al., 2005).

Stress-responsive sigma factors play an important role in regulating expression of both virulence genes and stress response genes in bacteria, including *L. monocytogenes*. The alternative sigma factor sigma B contributes to the ability of *L. monocytogenes* to survive and/or multiply under stressful conditions outside the host, e.g., acid, osmotic or oxidative stresses (Becker et al., 1998; Ferreira et al., 2001; Ferreira et al., 2003), low temperature (Becker et al., 2000) or carbon starvation (Ferreira et al., 2001). Sigma B also plays a role in the capacity of *L. monocytogenes* to persist within the host during the infectious process. It has been demonstrated that sigma B contributes to transcription of the virulence gene activator PrfA (Nadon et al., 2002). Characterization of the sigma B-dependent general stress regulon confirmed the broad role of this sigma factor. Indeed, the regulon includes genes encoding both general stress response proteins (e.g., the RNA-binding protein Hfq, glutamate decarboxylase GadB, general stress protein Ctc, and the glutathione reductase), and virulence factors (e.g., the internalins InlA and InlB, the bile salt hydrolase Bsh, the bile exclusion system BilA and the stress-responsive solute transporter OpuC (Sleator et al., 2001b; Kazmierczak et al.,

2003; Sue et al., 2003; Christiansen et al., 2004; Kim et al., 2004; Sleator et al., 2005a). *Listeria monocytogenes* stress response is also controlled by CtsR, a transcriptional repressor of *clpC*, *clpE* and *clpP*. A *ctsR* deletion mutant was not affected for virulence in mice and displayed an increased survival at high temperature and under salt stress (Nair et al., 2000). Finally, the regulatory RNA-binding protein Hfq is required for resistance to osmotic and ethanol stress, and full virulence in mice (Christiansen et al., 2004).

Gene Regulation in *Listeria*

Analysis of the complete genome sequence of *L. monocytogenes* EGDe revealed its extraordinary regulatory capacity as 201 regulatory proteins have been identified (Glaser et al., 2001). The *L. monocytogenes* genome contains the highest proportion of regulatory genes (7%) after that of *Pseudomonas aeruginosa* (8.4%) (Stover et al., 2000). This observation is in line with the fact that *L. monocytogenes* is an ubiquitous, opportunistic pathogen that needs a variety of combinatorial pathways to adapt its metabolism to a given niche. However, only a few of these regulators have been studied experimentally.

TWO-COMPONENT SYSTEMS The *L. monocytogenes* genome contains several two-component systems consisting of 15 histidine kinases and 16 response regulators. Several of them have been studied in detail: *lisR/lisK* (Cotter et al., 1999; Cotter et al., 2002), *cheY/cheA* (Flanary et al., 1999), *agrA/agrC* (Autret et al., 2003), *cesR/cesK* (Kallipolitis et al., 2003) and *virS/virR* (Mandin et al., 2005). The LisR/LisK system is involved in acid, ethanol and oxidative stress, and the inactivation of *lisRK* resulted in a slight decrease of virulence (Cotter et al., 1999). The LisRK signal transduction system is also involved in the sensitivity of *L. monocytogenes* to nisin and cephalosporins (Cotter et al., 2002). The genes regulated by this system are a putative penicillin-binding protein (*lmo2229*), a histidine kinase (*lmo1021*), and a protein of unknown function (*lmo2487*). A novel role for the two-component regulatory system LisRK in osmosensing and osmoregulation has been shown (Sleator and Hill, 2005b). Furthermore, *htrA*, a gene linked to osmotolerance and virulence potential in *L. monocytogenes*, was reported to be under the transcriptional control of LisRK (Stack et al., 2005).

Insertional inactivation of the *L. monocytogenes cheYA* operon abolished response to oxygen gradients and reduced flagellin expression and affected the ability of *L. monocytogenes* to attach to the mouse fibroblast cell line 3T3 (Flanary et al., 1999). A deletion mutant *cheA*

had impaired swarming and the *cheY* and *cheYA* double mutants were unable to swarm on soft agar plates, suggesting that *cheY* and *chaA* genes encode proteins involved in chemotaxis (Dons et al., 2004). Autret and colleagues identified by signature-tagged mutagenesis the *agrABCD* locus (Autret et al., 2003). The production of several secreted proteins was modified, indicating that the *agr* locus influenced protein secretion. Although the ability of the mutant to invade and multiply in cells in vitro was not affected, virulence of the *agrA* mutant was affected in the mouse model, indicating that the *agr* locus is involved in virulence of *L. monocytogenes* (Autret et al., 2003).

Kallipolitis and colleagues inactivated five putative response regulators identified by using degenerate primers in *L. monocytogenes* strain LO28 (Kallipolitis et al., 2003). These correspond to the genes *lmo2583*, *lmo2678/kdpE*, *lmo2501/phoP*, *lmo2422/cesR*, and *lmo1377/lisR*. Three of these putative response regulators, *lmo2678/kdpE*, *lmo2422/cesR*, and *lmo1377/lisR*, contributed to pathogenicity in a mouse infection model either by intragastric or intraperitoneal injection. Recently, *cesRK* was studied in more detail (Kallipolitis et al., 2003), showing that this two-component system responds to the presence of cell wall-acting antibiotics and affects ß-lactam resistance.

The new two-component system of *L. monocytogenes*, named VirS/VirR, which is necessary for virulence, was recently identified using signature-tagged mutagenesis (Mandin et al., 2005). A transcriptomic analysis revealed that VirS controls the expression of 108 other genes, probably by crosstalking with another response regulator, and that 12 genes are regulated by VirR, including the *dlt* operon (Mandin et al., 2004), previously shown to be important for *L. monocytogenes* virulence (Abachin et al., 2002). A conserved DNA sequence located upstream of all the transcriptional units regulated by VirR was identified by in silico analysis, probably representing the DNA binding site of VirR. The role of all sixteen putative two-component systems of *L. monocytogenes* was undertaken systematically, by the introduction of in frame deletions into 15 out of the 16 response regulator genes and the resulting mutants were characterized. With one exception, the deletion of the individual response regulator genes has only minor effects on *in vitro* and *in vivo* growth of the bacteria. The mutant carrying a deletion in the orthologue of the *Bacillus subtilis* response regulator gene *degU* showed reduced virulence in mice, indicating that DegU is involved in the regulation of virulence-associated genes (Williams et al., 2005). Knudsen and colleagues have shown that the DegU response regulator is a

pleiotropic regulator involved in expression of both motility at low temperature and in vivo virulence in mice (Knudsen et al., 2004).

PrfA—Key Regulator of *Listeria monocytogenes* Virulence Genes The PrfA (positive regulatory factor A) protein of *L. monocytogenes* functions as a master regulator, which is required and directly involved in the control of the differential expression of the *L. monocytogenes* virulence genes. PrfA is a 237-amino acid protein encoded by the first gene of the virulence gene cluster of *L. monocytogenes* whose expression is under the control of this transcriptional regulator (Leimeister-Wachter et al., 1990; Mengaud et al., 1991b; Chakraborty et al., 1992; Dramsi et al., 1993). The *prfA* gene lies downstream from and is co-transcribed with *plcA-prfA* is transcribed as either a monocistronic or a bicistronic *plcA-prfA* transcript, thereby creating an autoregulatory loop essential for the appropriate expression of virulence genes (Mengaud et al., 1991b) (Fig. 44). Evidence for an overexpression of PrfA inside cells has been observed (Klarsfeld et al., 1994; Renzoni et al., 1999).

Molecular and Structural Features On the basis of structural and functional features shared with the cAMP receptor protein (Crp) of *E. coli*, PrfA is clearly a member of the Crp/Fnr (fumarate
Fig. 44. The PrfA regulon in *L. monocytogenes*. *prfA*: positive regulatory factor; *plcA*: phosphatidylinositol phospholipase C; *hly*: listeriolysin O; *mpl*: metalloprotease; *actA*: actin-polymerization protein; *plcB*: broad-range phospholipase C (lecithinase); *inlA*, *inlB*: large cell wall associated internalins A and B; *inlC*: small secreted internalin, *hpt*: hexose phosphate transporter; *bsh*: bile salt hydrolase; and + indicates transcriptional induction. nitrate reductase regulator) family of transcriptional regulators (Lampidis et al., 1994). Interestingly this family of regulators seems to be of particular importance for *Listeria* insofar as there are 15 Crp/Fnr family members in *L. monocytogenes* in contrast to only one in *B. subtilis* and two in *E. coli* (Glaser et al., 2001). Figure 45 shows the domain organization of PrfA from *L. monocytogenes* compared to that of Crp from *E. coli*. In the N-terminal domain, both contain several ß-sheets delimited by glycine residues forming a ß-roll structure and an α-helical region. In Crp, both are involved in binding of the cofactor cAMP. In PrfA several of the amino acids required for cAMP binding are not conserved and the role of this ß-roll structure is not known yet. Two of the three activating regions of Crp, which mediate the interaction with the RNA polymerase, are conserved in PrfA (Fig. 45). PrfA has in its C-terminal region a DNA-binding helix-turn-helix (HTH) region with 70% similarity to the corresponding HTH in Crp. The crystal structure of PrfA has recently been solved confirming the above information (Thirumuruhan et al., 2003; Protein Data Bank (http://www.rcsb.org/pdb), accession code 1OMI; Eiting et al., 2005). Activation of genes by PrfA requires binding of this HTH region to a 14-bp palindromic sequence present at PrfA regulated promoters, the PrfA-box (Freitag et al., 1993; Bockmann et al., 1996; Sheehan et al., 1996). This palindrome is centered at position –41 relative to the transcriptional start site and partially over-laps the –35 promoter regions. It was shown that the two critical elements of PrfA-dependent promoters, the PrfA-box and the –10 box, can be functionally exchanged as long as the distance in between is maintained to 22 or 23 bp (Luo et al., 2005). PrfA activates all genes of the virulence gene cluster (*prfA*, *plcA*, *hly*, *mpl*, *actA* and *plcB*) as well as the *inlA* and *inlB* (Dramsi et al., 1997), *inlC* (Engelbrecht et al., 1996; Lingnau et al., 1996), *bsh* (Dussurget et al., 2002) and *hpt* (*uhpT*) genes (Chico-Calero et al., 2002). Table 6 shows the PrfA-box sequences of these PrfA regulated virulence genes in *L. monocytogenes*. That the PrfA box is indeed the recognition sequence for PrfA has been suggested by the effect of mutations in this sequence (Freitag et al., 1992). Further evidence came from gel retardation assays and in particular from DNAse I protection experiments (Bockmann et al., 1996). At the C-terminus, PrfA has an extension as compared to Crp with the characteristics of a leucine zipper (Lampidis et al., 1994). However, different studies indicate that the mechanisms regulating the *L. monocytogenes* virulence genes are very complex and show that PrfA is not the only regulatory factor. By using an *in vitro* transcription assay for *L. monocytogenes* genes, it was shown that overlapping PrfA-dependent and -independent promoters that are differentially activated by GTP are present for the PrfA-dependent genes *inlC* and *mpl*, indicating that these genes are not solely regulated by PrfA. Furthermore, PrfA-independent transcription of

inlC and *mpl* was shown to be strongly inhibited by PrfA because of the close proximity of the PrfA binding site to the −35 box (Luo et al., 2004). Shen and Higgins demonstrate that the *hly* 5′ UTR plays a critical role in regulating expression of LLO during intracellular infection (Shen and Higgins, 2005). They suggest that the *hly* 5′ UTR functions independently of PrfA-mediated transcription and can enhance expression of cis-associated genes through a mechanism that appears to act at both a post-transcriptional and post-translational level. Deletion of the hly 5′ UTR, while retaining the hly ribosome binding site, had a moderate effect on LLO production during growth in broth culture, yet resulted in a marked decrease in LLO levels during intracellular infection (Shen and Higgins, 2005).

Functional Changes Due to Alterations in Defined Positions   Specific amino acid changes in PrfA correlates with high or low level of hemolytic activity, because of high- or low-level expression of the *hly* gene. A Gly145Ser substitution (Fig. 45) is responsible for a high hemolytic phenotype (Ripio et al., 1997b). This mutation freezes PrfA in its active conformation leading to the expression of a constitutively active PrfA* form (Ripio et al.,1996). The crystal structure of PrfA* has been solved and compared to that of wild-type PrfA, showing that the HTH motifs and adopt a conformation similar to cAMP-induced Cap, which favors DNA binding (Eiting et al., 2005). The correlation of the high hemolytic phenotype with the altered PrfA protein is also supported by the observation that the transfer of the *prfA** gene to a strain with low hemolytic activity shifts it to a strain with high hemolytic activity (Bohne et al., 1996; Ripio et al., 1997b). A Leu140Phe mutation and an Ile45Ser mutation, mapping to the N-terminal β-roll structure, also cause a constitutive overexpression of the PrfA regulon (Vega et al., 2004; Wong and Freitag, 2004). Wong and Freitag report that the mutation Leu140Phe results in the aggregation of *L. monocytogenes* in broth culture and, unlike previously described *prfA* mutations, appears to be slightly toxic to the bacteria (Wong and Freitag, 2004). As shown by Sheehan and colleagues, a Ser183Ala exchange also leads to increased binding of PrfA causing enhanced expression of virulence genes, whereas a Ser184Ala exchange leads to decreased binding of PrfA to its target sequence and thus to reduced expression of virulence genes (Sheehan et al., 1996) (Fig. 45). Shetron-Rama and colleagues selected *L. monocytogenes* mutants expressing high levels of *actA* during *in vitro* growth after chemical mutagenesis (Shetron-Rama et al., 2003). This led to the identification

of two different amino acid substitutions within PrfA (Glu77Lys and Gly155Ser), which also appear to lock PrfA in its activated state. Both *prfA* Glu77Lys and *prfA* Gly155Ser strains are more efficient than wild-type bacteria in gaining access to the host cell cytosol and in initiating the polymerization of host cell actin, and both are capable of mediating LLO-independent lysis of host cell vacuoles in cell lines for which *L. monocytogenes* vacuole disruption normally requires LLO activity (Mueller and Freitag, 2005). Positive selection of mutations leading to loss or reduction of transcriptional activity of PrfA led to the identification of mutations in three regions of the PrfA protein: 1) between amino acids 58–67 in the β-roll domain, 2) between amino acid 169–193, corresponding to the DNA-binding HTH motif, and 3) in the 38 C-terminal amino acids of PrfA, which form the putative leucine-zipper-like structure. Mutations in the HTH motif and the leucine-zipper-like structure lead to PrfA proteins unable to bind to the PrfA-binding site (Herler et al., 2001).

Physicochemical Parameters Influencing PrfA A number of physicochemical parameters are known to affect the expression of PrfA-dependent genes. For example, elevated iron concentrations in the medium repress transcription of *hly* and *actA*, whereas growth in activated charcoal-containing BHI or in minimum essential medium results in induction of *prfA* and PrfA-dependent gene expression. Furthermore, the presence and utilization of different carbohydrates has a remarkable impact on the virulence of *L. monocytogenes* (Kreft and Vazquez-Boland, 2001). For instance, growth on glucose-1-phosphate (G-1-P) as sole carbon source is strictly PrfA-dependent (Ripio et al., 1997a). It was shown that the PrfA-dependent utilization of this compound is necessary for efficient cytosolic replication of *L. monocytogenes* (Chico-Calero et al., 2002). An interesting observation is that metabolizable unphosphorylated sugars inhibit the expression of PrfA-dependent virulence genes. This mechanism was first discovered with cellobiose, but later any fermentable carbohydrate was found to trigger the downregulation of PrfA-dependent virulence genes. CcpA (catabolite control protein A) was suggested to be an important element of carbon source regulation in *L. monocytogenes*, but utilizable sugars still downregulate the expression of *hly*. In a *ccpA* mutant, CcpA does not seem to be involved in carbon source regulation of virulence genes (Behari and Youngman, 1998). Interestingly, in the presence of cellobiose, PrfA is fully expressed, suggesting that PrfA is post-transcriptionally modified (Renzoni et al., 1997)

and can switch between a transcriptionally active and inactive form upon interaction with an hypothetical activating factor (Renzoni et al., 1997; Ripio et al., 1997b, Vega et al., 1998). This is also suggested by the fact that *L. monocytogenes* strains producing a constitutively active PrfA form are refractory to sugar-mediated virulence gene expression (Ripio et al., 1997a). Isolation of mutants that exhibit high levels of PrfA-controlled gene expression in the presence of cellobiose or glucose led to the identification of mutations in two different genetic loci, *gcr* and *csr*, both unlinked to the major virulence cluster. A mutation in *gcr* deregulates the expression of PrfA-controlled genes in the presence of several repressing sugars and other environmental conditions, a phenotype similar to that of a Gly145Ser substitution in PrfA itself. A mutation in the *csr* locus, within *csrA*, results in a cellobiose-specific defect in virulence gene regulation. Mutations in both *gcr* and *csr* are required for full relief of cellobiose-mediated repression of the PrfA regulon, suggesting the existence of two semi-independent pathways for cellobiose-mediated repression (Milenbachs Lukowiak et al., 2004). Expression of *prfA* and *hly* in murine macrophage-like J774.1 cells, with or without activation by IFN-γ plus LPS, showed that expression of *hly* inside activated macrophage was abolished by addition of SOD and catalase, suggesting that reactive oxygen intermediates contribute to the upregulation of *prfA* and *hly* transcriptions. Moreover, exposure of *L. monocytogenes* to H_2O_2 dramatically enhanced the expression of both *prfA* and *hly* mRNAs, suggesting that oxygen radicals generated in activated macrophages provide a positive signal for up-regulation *prfA* and the *prfA*-regulated virulence genes in *L. monocytogenes* (Makino et al., 2005).

The PrfA-regulon Analyzed at the Genome Level The PrfA-regulon and the influence of physicochemical factors on gene regulation by PrfA have been studied at the complete genome level by a transcriptomics approach (Milohanic et al., 2003; Rauch et al., 2005). Using whole-genome arrays based on the sequenced *L. monocytogenes* EGDe strain (Glaser et al., 2001), the expression profiles of two *L. monocytogenes* wild-type strains (EGDe and P14*) were compared to those of their *prfA*-deleted mutant strains. The study of three different growth conditions, rich-medium (BHI), BHI supplemented with active charcoal, and BHI supplemented with cellobiose allowed three groups of genes differently regulated by PrfA to be identified. One group included the already known virulence genes and two newly identified genes (*lmo2219*

and *lmo0788*), which all contain a PrfA-box. These results indicate that the core set of genes directly regulated by PrfA is quite small (i.e., in the conditions tested, only 12 genes [*hly*, *mpl*, *actA*, *plcB*, *plcA*, *prfA*, *inlA*, *inlB*, *inlC*, *hpt*, *lmo2219*, and *lmo0788*]). Most interestingly, a second group of genes encoding a putative sugar transport system was shown to be negatively regulated by PrfA, indicating that PrfA can also act as a repressor. The most surprising result was the identification of a third group of 53 genes (group 3), which was regulated but did not contain a PrfA binding site. In depth analysis revealed sigma B like promoters in front of nearly all the genes of this group 3, suggesting interplay between PrfA and sigma B (Milohanic et al., 2003). This finding is substantiated by a report by Nadon and colleagues who reported the P_2prfA is a sigma B dependent promoter (Nadon et al., 2002). A transcriptome analysis comparing a wild-type and a *sigB* deleted mutant strain using focused microarrays containing 208 putative sigma B regulated genes and known *L. monocytogenes* virulence genes showed that sigma B regulates the stress response. It also confirmed the previous implication of sigma B in regulation of virulence functions (Kazmierczak et al., 2003).

Temperature Regulation of PrfA Expression Pathogenic Listeriae face a sudden increase in temperature during the transition from the environment to a warm-blooded host. This temperature shift correlates with a maximal expression of the virulence genes at 37°C but nearly no expression at 30°C. The low expression of virulence genes coincides with the absence of PrfA protein, although the *prfA* gene is still transcribed (Leimeister-Wachter et al., 1992; Renzoni et al., 1997; Johansson et al., 2002). At low temperatures, *prfA* is transcribed from its own promoter, giving rise to a monocistronic *prfA* transcript. At 37°C, transcription originates both from the *prfA* promoter and from the PrfA-dependent *plcA*-promoter (Fig. 46). However, the absence of PrfA protein at temperatures lower than 30°C is not due to a general untranslatability of the *prfA* monocistronic messenger. The mechanisms underlying thermoregulated production of PrfA have recently been elucidated. At low temperature, the untranslated mRNA region (UTR) preceding *prfA* forms a secondary structure, which masks the ribosome-binding site. At high temperature, the structure is destabilized (Fig. 47). Thus, a RNA "thermosensor" controls the expression of virulence genes in *L. monocytogenes* (Johansson et al., 2002).

Regulation through Sigma Factors L. monocytogenes is predicted to contain only five sigma factors in comparison to 18 in *B. subtilis* (Kunst
Fig. 46. Transcription of the *prfA* (positive regulatory factor) gene at both 20°C and 37°C. A) Schematic representation of *prfA* transcription. The mono- and the bicistronic mRNA at 20°C and 37°C are indicated as dotted flashes under the map. The intergenic region between *plcA* (phosphatidylinositol phospholipase C) and *prfA* are enlarged above the map indicating the transcriptional start (+1) and the *prfA*-UTR (untranslated region). B) Northern blot analysis of *prfA* transcription. Wild-type *L. monocytogenes* strain LO28 was grown to late logarithmic phase in brain–heart infusion (BHI) media at either 20° or 37°C. From Johansson et al. (2002), with permission.

Fig. 47. Model of mechanism underlying thermoregulated expression of PrfA (positive regulatory factor). The *prfA*-UTR (untranslated region) forms a secondary structure at low temperatures (30°C) masking the ribosomal region of *prfA*, thus preventing the binding of the ribosome. PrfA is not translated and virulence genes are not expressed. At high temperatures (37°C) the *prfA*-UTR partially melts, and thereby permits binding of the ribosome to the Shine-Dalgarno sequence. From Johansson et al. (2002), with permission.
et al., 1997) and 13 in *Mycobacterium tuberculosis* (Cole et al., 1998). These are similar to *B. subtilis* SigA, SigB, SigH, SigL (RpoN, sigma 54) and ECF-type sigma factors. Sigma 54 of *L. monocytogenes* has been described to be involved in sensitivity to antibacterial peptides, the subclass IIa bacteriocins (Robichon et al., 1997). One sigma 54-dependent operon, *mptACD*, has been characterized in details in *L. monocytogenes*. Its expression is controlled by the ManR activator, which belongs to the LevR family (Dalet et al., 2001). The *mptACD* operon encodes the AB, C and D subunits of a PTS permease of the mannose family, EIItMan. The lack of *mptACD* expression, in a *mpt* or a *rpoN* mutant, leads to resistance of *L. monocytogenes* to subclass IIa bacteriocins. The EIItMan permease was thus proposed to be the receptor for these antibacterial peptides (Dalet et al., 2001; Duché et al., 2002; Gravesen et al., 2002). Study

of the role of the alternative sigma 54 factor by comparing the global gene expression and the protein content of *L. monocytogenes* strain EGDe suggested that sigma 54 is mainly involved in the control of carbohydrate metabolism in *L. monocytogenes* via direct regulation of the PTS activity, alteration of the pyruvate pool and modulation of carbon catabolite regulation (Arous et al., 2004).

The alternative sigma factor sigma B modulates the stress response of several Gram-positive bacteria, including *Bacillus subtilis* and the food-borne human pathogens *Bacillus cereus*, *L. monocytogenes* and *Staphylococcus aureus*. In all these bacteria, sigma B is responsible for the transcription of genes that can confer protection to the cell against adverse conditions. Upon exposure to stress, the stress has to be sensed and signaled through a regulatory cascade, leading to the activation of sigma B and, subsequently, to

the transcription of the set of sigma B-regulated genes (the Sigma B regulon). The encoded proteins perform specific functions, which protect the cell against stress. In *L. monocytogenes*, sigma B was shown to have a role in growth and survival under low temperatures, acid tolerance, survival under environmental, energy, and intracellular stress conditions (Becker et al., 2000; Wiedmann et al., 1998; Chaturongakul and Boor, 2004). This condition is of special interest for practical reasons, as chilled storage is often a crucial factor in the preservation of minimally processed foods. The deletion of *sigB* had only very minor effects on virulence, as tested in animals models (Wiedmann et al., 1998), even though several virulence factors in this organism are under the control of sigma B (see below). The *bsh* gene encoding the bile salt hydrolase and two genes from the internalin family, which contribute to bacterial entry are partially sigma B-dependent and also contribute to PrfA-mediated virulence in *Listeria monocytogenes* (Kazmierczak et al., 2003; Sue et al., 2003; Nadon et al., 2002; Milohanic et al., 2003). Furthermore, the central role of sigma B in the regulatory network is illustrated by the fact that sigma B can control other important regulatory proteins like the RNA-binding protein Hfq in *L. monocytogenes*. Hfq is thought to play a crucial role in the post-transcriptional regulation of gene expression by small RNAs and the dependency of this regulator on sigma B adds another level of complexity to the function of sigma B in *L. monocytogenes* (Christiansen et al., 2004).

Animal Models

Considerations for the Choice of an Adequate Animal Model An infection is a multistep process integrating a number of host and microbial variables. For this reason, comprehension of the pathophysiology of a human infection necessitates an animal model in which the infectious agent has the same cell and tissue tropism as in humans. Similarly, an animal model should allow observation of the same direct effects and indirect immunopathological damages occurring in humans. Such a model should allow testing the in vivo relevance of results acquired using more reductionist in vitro approaches. Ideally, both the microbial pathogen and the animal model should be genetically amenable, thus allowing assessment of the role of critical microbial and host factors during the infectious process. The genetic manipulation of both the pathogen and the host may lead to a better understanding of their respective contributions in the complex interplay that results in disease (Finlay, 1999; Harvill and Miller, 2000; Lecuit and Cossart, 2002).

Since animal listeriosis exists, animal species naturally infected by *L. monocytogenes* can be used as models to study the pathophysiology of human listeriosis. However, this also implies important technical limitations: the animals developing a disease closely resembling human listeriosis are not classical laboratory animals such as the rat or the mouse but rather farm animals such as sheep, cattle and goats. As for other human diseases, the murine model became the most widely used animal model in mammal biology. Indeed, mice have all the necessary qualities to make them good laboratory animals: smallness, resistance and adaptation to captivity, easy reproduction, abundant offspring, short gestation period, and a physiology and pathophysiology in most respects comparable to humans. However, certain human pathogens are not mouse pathogens, and mouse disease induced by human pathogens can be manifestly different from the actual human disease. With this in mind, the mouse is frequently regarded as an unsatisfactory model for the study of human infectious diseases, which still continues to be used in the absence of better models (Lecuit and Cossart, 2002).

A review of the literature did not find reports of symptomatic natural *L. monocytogenes* infection in mice and rats. Experimentally, the mouse, like the rat, which is phylogenetically extremely close to the mouse species, cannot be easily infected with *L. monocytogenes* by the oral route. Most studies using mice or rats fail to induce a reproducible lethal infection after oral infection with *L. monocytogenes*, even using extremely high inocula (Zachar and Savage, 1979; Roll and Czuprynski, 1990; Okamoto et al., 1994; Gaillard et al., 1996; MacDonald and Carter, 1996; Marco et al., 1997; Pron et al., 1998; Huleatt et al., 2001; Manohar et al., 2001). This implies that one has to consider with caution results of in vivo studies using dose-response mathematical models to determine the theoretical lethal dose in humans after oral ingestion of contaminated food (Haas and Thayyar-Madabusi, 1999).

To circumvent the low susceptibility of mice infected via the oral route, alternate routes of administration were used, although they do not mimic the natural route for infection. They include intravenous and intraperitoneal, or more rarely intranasal, subcutaneous, conjunctival, intracardiac or intracerebral routes, not only in mice but also in guinea pigs, rabbits and sheep (Kautter et al., 1963; Racz et al., 1970; Khan et al., 1972; Dustoor et al., 1977; Scheld et al., 1979; Prats et al., 1992). In mice, inoculation via the intravenous rather than the oral route can produce a lethal infection, and thus allows the determination of the LD_{50} and comparison of the virulence of various mutants. This route of

administration was particularly instrumental in characterization of most *L monocytogenes* virulence genes (Gaillard et al., 1986; Kathariou et al., 1987; Cossart et al., 1989b; Domann et al., 1992; Kocks et al., 1992; Raveneau et al., 1992). It also allowed demonstrating that immunosuppression, young age and gravidity were associated with a reduced LD_{50}. Finally, it revealed granulomatous hepatitis due to intravenously-acquired murine listeriosis was similar to that observed in *granulomatosis infantiseptica* (Luft and Remington, 1982; Stelma et al., 1987; Genovese et al., 1999). However, this symptomatic septicemic infection seems different from what is observed in the human species, for which the phase preceding the feto-placental or CNS infection is mostly clinically silent.

Infection by the intravenous route in the mouse model also allowed the discovery of cellular immunity and its cellular basis (CD8+ lymphocytes) (Mackaness, 1962; Mackaness and Hill, 1969; North, 1969; Pearson and Osebold, 1973; Kaufmann, 1988). The pioneering studies carried out by Mackaness in the 1960s made *L. monocytogenes* one of the best-characterized and most instrumental models of intracellular microbes (Mackaness, 1962; Mackaness and Hill, 1969). However, the low capacity of *L. monocytogenes* to infect mice via the oral route has limited the use of *L. monocytogenes* to the field of systemic immunity at the expense of mucosal immunity. This model of infection also made it possible to demonstrate that genetic background played a part in the susceptibility to *L. monocytogenes*, since BALB/c mice are more sensitive to *L. monocytogenes* than C57 BL/6 following intravenous inoculation (Cheers and McKenzie, 1978). The molecular mechanisms underlying these susceptibility differences are unknown. Their identification should lead to a better understanding of the human inter-individual variation in susceptibility to *L. monocytogenes* (Boyartchuk et al., 2001).

ADDRESSING THE SPECIES-SPECIFICITY OF *L. MONOCYTOGENES* IN ANIMAL MODELS A number of human pathogens exhibit stringent host specificity. For some of them, the molecular basis of their restricted host-tropism has been at least partially deciphered. It implicates the species-specific interaction of a microbial ligand with its cellular receptor(s), as demonstrated for viruses such as the poliovirus, the measles virus, HIV and hepatitis C virus, but also for bacteria such as *Neisseria gonorrhea* and *Neisseria meningitidis*, and more recently *L. monocytogenes* (Dalgleish et al., 1984; Mendelsohn et al., 1989; Dorig et al., 1993; Alkhatib et al., 1996; Dragic et al., 1996; Virji et al., 1996; Chen et al., 1997; Gray-Owen et al., 1997; Pileri et al., 1998; Lecuit et al.,

1999; Lecuit et al., 2001b). Study of a species-specific ligand-receptor interaction, thought to play a critical role in human infection, should be possible in an animal model that allows this interaction to occur. Two possibilities exist to establish such a model: the simplest one is to identify an animal species in which the interaction does occur (such as cattle, sheep and goats for *L. monocytogenes*) and to use it as a model. A more sophisticated approach is to generate a genetically modified animal, generally a transgenic mouse line that expresses the human receptor and to look at the effect of the transgene expression on the infectious process. The human receptor can be expressed either in place of or in addition to its nonfunctional mouse orthologue, either ubiquitously or under the control of a tissue-specific promoter that drives expression of the transgene in the cell types targeted by the pathogen during the human infection (Lecuit and Cossart, 2002).

As mentioned above, in mice, oral inoculation is a very inefficient way to trigger systemic listeriosis, because *L. monocytogenes* translocation across the intestinal barrier is low and not higher than that of the closely related nonpathogenic species *L. innocua*. The few detectable foci of bacterial multiplication are restricted to Peyer's patches, areas that contain M-cells, i.e., cells possessing a phagocytic activity. Thus, *L. monocytogenes* is not an enteropathogen for mice. Moreover, in mice, the brainstem and the feto-placental unit do not appear as elective targets, as is the case in humans (M. Lecuit, unpublished results).

Following mouse intravenous inoculation, LLO, ActA, PLC-A, and PLC-B but not internalin act as virulence factors. Indeed, despite the well-established prominent role of internalin in the internalization process in vitro, its role in vivo has long remained elusive since an internalin mutant behaves as its wild-type parent after mouse intravenous or oral inoculation. Strikingly, shortly after the discovery of human E-cadherin as the internalin receptor, it was established that, in contrast to human E-cadherin, mouse E-cadherin is unable to promote entry of *L. monocytogenes* into cells. This specificity was shown to depend on a single amino acid of the mature E-cadherin peptidic chain, the sixteenth, which is proline in humans and glutamic acid in mice. This result led to the conclusion that *L. monocytogenes* exhibits a species-specificity towards its host, and that the mouse model is inappropriate to study internalin function (Lecuit et al., 1999). Similarly, InlB was shown to be species-specific being able to promote entry and ruffling in human and mice cells but not in guinea pig and rabbit cells. As a consequence, no role could be demonstrated for

InlB in guinea pigs and rabbit infections although it played a role in liver and spleen colonization in mice (Khelef et al., in press).

A more appropriate animal species for studying the putative role of internalin interaction with E-cadherin in vivo turned out to be the guinea pig. Indeed, internalin-dependent entry of *L. monocytogenes* was demonstrated in cultured guinea pig cells expressing E-cadherin, harbouring a proline at position 16 as human E-cadherin (Lecuit et al., 1999). Moreover, induction of a gastroenteritis by *L. monocytogenes* resembling that observed in humans was observed in the guinea pig (Racz et al., 1972; Dalton et al., 1997; Pron et al., 1998; Aureli et al., 2000; Lecuit et al., 2001b). In addition, it is able to cross the intestinal barrier and induce a dose- and internalin-dependent lethality following dissemination into the systemic circulation (Lecuit et al., 2001b). Yet, this model remains inappropriate to study concomitantly the role of both InlA and InlB. To investigate the role of the internalin-E-cadherin interaction in the ability of *L. monocytogenes* to cross the intestinal barrier, a transgenic mouse model was generated. The human E-cadherin cDNA was placed under the control of the promoter of the intestinal fatty acid binding protein (iFABP) gene, which is exclusively active in post-mitotic nonproliferative small intestinal enterocytes. In this transgenic model, *L. monocytogenes* directly targets enterocytes by interacting with enterocytic E-cadherin. This interaction leads to *L. monocytogenes* internalization into these cells and allows the subsequent crossing of the intestinal barrier, followed by bacterial multiplication in the small intestine lamina propria, and dissemination to mesenteric lymph nodes, liver and spleen (Fig. 48). This is the first transgenic model to reveal the role of a bacterial virulence factor and to demonstrate its critical implication in a key step of an infection process. The enterocyte-restricted human E-cadherin expression has been critical to demonstrating at a molecular level the direct in vivo targeting of enterocytes by *L. monocytogenes* and the genuine enteropathogenicity of *L. monocytogenes*. Furthermore, this transgenic model not only provides the molecular explanation for the innocuity of *L. monocytogenes* in mice following oral infection but also explains the enteropathogenicity of *L. monocytogenes* in guinea pigs, and most probably in humans (Lecuit et al., 2001b). A mouse model for orally acquired listeriosis is now available. The host response to listeriosis can now be studied in depth from its starting point (the intestinal lumen) using the combined approaches of microbial genetics, transgenesis, gnotobiology, and functional genomics, coupled to laser capture microdissection, as described in the study of host
Fig. 48. *Listeria monocytogenes* multiplication within the lamina propria of a small intestinal villus of an *iFABP-hEcad* (intestinal fatty acid binding protein-human E-cadherin) transgenic mouse 48 h after intragastric inoculation. A section through the small intestine of an *iFABP-hEcad* transgenic mouse is immunolabeled with rabbit anti-*L. monocytogenes* R11 polyclonal antibody and the *Listeria* are revealed with anti-peroxidase antibodies (red). *Listeria monocytogenes* have crossed the intestinal barrier and replicate in the lamina propria, a phenomenon that is never observed in nontransgenic mice. Scale bar 10 μm. From Lecuit et al. (2001b), with permission.

responses to commensal bacteria by Hooper and Gordon (2001). The availability of the *L. monocytogenes* genome, together with that of its nonpathogenic counterpart *L. innocua*, will probably be very helpful in identifying additional virulence factors in this new model. This system, however, as the models for human viral infections presented above, has its limits. These were anticipated when the transgenesis strategy was designed. Indeed, since human E-cadherin expression is restricted to enterocytes in the *iFABP*-human E-cadherin transgenic mice, the role of other cell types expressing E-cadherin (such as dendritic cells, hepatocytes, microvascular endothelial cells, epithelial cells of the choroid plexus, and cytotrophoblastic cells, all of which are putative *L. monocytogenes* targets during human listeriosis) cannot be addressed. Mice overcoming this limitation are now being generated by changing the codon for glutamic acid 16 of mouse E-cadherin at the endogenous mouse E-cadherin locus *Cdh1* on chromosome 8 into a codon for proline. This unique change in murine E-cadherin has indeed been shown to be sufficient to convert mouse E-cadherin into an internalin receptor in transfected cultured cells expressing this modified Glu16Pro mouse E-cadherin (Lecuit et al., 1999). The new transgenic mouse line should permit the study of the tropism of *L. monocytogenes* for the CNS and the feto-placental unit (which is responsible for the lethality of human listeriosis) and to further investigate the role of internalin E-cadherin interaction in extraintestinal tissues. This model

should also allow addressing the role of InlB in mice after oral infections. The importance of these future studies is emphasized by the results of our recent epidemiological investigations, which showed that 100% of *L. monocytogenes* isolates obtained from pregnancy-associated listeriosis and collected in a one-year period express a functional internalin, whereas only 65% of food isolates collected during the same period express functional internalin. These results strongly argue in favor of a role for internalin in crossing the maternofetal barrier (Jacquet et al., 2004). This hypothesis has now been confirmed experimentally (Lecuit et al., 2004). Recent studies using different *L. monocytogenes* strains reveal that, in contrast to strains from other serovars, serotype 4b epidemic strains appear to be able to cause systemic infection in mice infected orally. This suggests that serovar-specific virulence factors might be playing a role in mouse susceptibility to orally acquired listeriosis. These observations highlight that the properties of an animal model may vary from strain to strain of a single bacterial species (Czuprynski et al., 2003).

Comparative Genomics

Comparative genomics and related technologies are helping to unravel the molecular basis of pathogenesis, host range, evolution and phenotypic differences of Listeriae. The first application of genomics to *Listeria* research was the determination by a consortium of 10 European laboratories of the complete genome sequences of the pathogen *L. monocytogenes* (strain EGDe) and the closely related nonpathogenic species *L. innocua* (strain CLIP11626) (Glaser et al., 2001). The availability of these two sequences (see ListiList Worldwide Web Server (http://genolist.pasteur.fr/ListiList/)) opens the way to comparative and functional genomics and the use of new approaches like bioinformatics, microarrays and proteomics to gain functional information (Fig. 49). Additional sequence information is available as a second *L. monocytogenes* isolate, strain F2365 (Scott A), is being sequenced by the TIGR {Technical Institute of Genomic Research} in collaboration with the USDA. Furthermore, the determination of the genome sequences of *L. ivanovii*, *L. seeligeri*, *L. welshimeri* and *L. grayi* strains by the German PathoGenomik network in collaboration with the Institut Pasteur are nearing completion. The availability of these different genome sequences of Listeriae will pave the way for in-depth comparative genomics and the identification of unknown virulence determinants.

Circle 3, G/C bias (G1C/G–C) of *L. monocytogenes*. Circle 4, G1C content of *L. monocytogenes* (32.5% G1C in light yellow, 32.5–43.5% in yellow, and >43.5% G1C in dark yellow). The scale in megabases is indicated on the outside of the genome circles, with the origin of replication at position 0. From Glaser et al. (2001), with permission.

monocytogenes EGDe genome comprises 2,944,528 bp with an average G+C content of 39% and 2853 predicted protein-coding genes. The *L. innocua* CLIP11626 chromosome is 3,011,209 bp long with an average G+C content of 37% and 2981 predicted protein-coding genes (Glaser et al., 2001). Analysis of the two *Listeria* genomes allowed common and particular features of Listeriae to be determined, as well as differences between a pathogenic and a nonpathogenic *Listeria* strain. One interesting common feature is the finding that 2587 of the 2853 *L. monocytogenes* genes have an orthologue in the *L. innocua* genome (Glaser et al., 2001). Furthermore, a perfect conservation of the order as well as the relative orientation of these orthologous genes was identified, indicating a high stability in the genome organization of Listeriae and a close phylogenetic relationship of the two *Listeria* genomes (Buchrieser et al., 2003). However, despite this high number of common genes, considerable differences in gene content exist

between the two *Listeria* genomes, some of which are undoubtedly related to the ability of *L. monocytogenes* to cause disease in humans and animals.

A particular feature of the *Listeria* genomes is the presence of an exceptionally large number of surface proteins, as 4.8% of all predicted genes of *L. monocytogenes* EGDe and 4.3% of the *L. innocua* genome code for surface proteins. Interestingly, the differences between the two *Listeria* genomes are also the most pronounced within genes encoding surface proteins, in particular among those that encode proteins possessing a peptidoglycan anchoring domain (LPXTG motif) (Navarre and Schneewind, 1999). The *L. monocytogenes* EGDe genome encodes 41 such proteins, 19 of which are absent from the *L. innocua* CLIP11626 genome. In contrast *L. innocua* contains 34 LPXTG proteins, 14 of which are *L. innocua* CLIP11626 specific (Glaser et al., 2001; Cabanes et al., 2002). The difference in surface proteins may be related to the additional capacity of *L. monocytogenes* to interact with various eukaryotic cell types.

Besides surface proteins, an abundance of transport proteins (331 genes in *L. monocytogenes* EGDe and 313 in *L. innocua* CLIP11626) and an extensive regulatory repertoire (209 genes in the *L. monocytogenes* EGDe and 203 in *L. innocua*) are characteristic for the *Listeria* genomes. These data correlate with the capacity of *Listeria* to adapt and respond to a wide variety of different environments and to its property to colonize a broad range of ecosystems. A high percentage of the encoding capacity of the two *Listeria* genomes is dedicated to transport proteins (11.6% and 11.4%, respectively) and to regulatory proteins (7.3% and 7.1%, respectively). However, the differences between the two *Listeria* genomes are not as pronounced as the differences identified in the surface protein repertoire, suggesting their implication primarily in specific features common to the lifestyle of Listeriae outside a mammalian host.

SPECIES-SPECIFIC GENES AND STRAIN-SPECIFIC GENES: A GLOBAL VIEW The genome comparison of *L. monocytogenes* EGDe and *L. innocua* CLIP11626 identified a conserved genome organization and a high number of orthologous genes, but it also revealed the presence of 270 *L. monocytogenes* EGDe-specific genes (9.5%) and 149 *L. innocua* CLIP11626-specific genes (5%), when prophages were not taken into account. The *L. monocytogenes* EGDe-specific genes are present in 100 DNA fragments scattered throughout the entire chromosome, and the *L. innocua* CLIP11626 specific genes are clustered in 63 regions containing 1–7 genes (Glaser et al., 2001; Buchrieser et al., 2003). This particular

organization of a number of small regions within the *Listeria* genomes suggests that multiple acquisition, but also deletion events, have led to the present genome content. The question arises now whether these genes (e.g., the 41 genes of *L. monocytogenes* EGDe encoding for surface proteins with a LPXTG motif) are consistently present in all *L. monocytogenes* isolates or whether further differences exist among the different *L. monocytogenes* strains. To this end additional sequence information and comparative genomic approaches using the DNA-array technique were employed. *Listeria monocytogenes* strains belonging to different sub-groups other than the EGDe strain (serovar 1/2a), e.g., serovar 4b strains, exhibit considerable differences in their gene content. Indeed, about 8% of the genes are specific to this group of strains but absent from *L. monocytogenes* serovar 1/2a (Doumith et al., 2004a). These results are in line with a previous report (Herd and Kocks, 2001) that identified 39 specific gene fragments for the epidemic *L. monocytogenes* strain F4565 as compared to *L. monocytogenes* EGDe using a subtractive hybridization method. When comparing genes encoding for different protein families among the three *Listeria* strains sequenced (*L. monocytogenes* EGDe, *L. monocytogenes* serovar 4b, and *L. innocua* CLIP11262), the importance of the surface protein encoding genes, in particular those with a LPXTG anchor motif, was clearly underlined. Genes encoding proteins belonging to the LPXTG family showed the most pronounced differences among the strains. We identified a core gene pool of 20 genes encoding for LPXTG proteins and specific ones in each strain. This indicates that this protein family might be strongly implicated in strain-specific and species-specific features of Listeriae. These findings were further substantiated by the results obtained from DNA-DNA hybridization of 93 *L. monocytogenes* strains and 20 strains belonging to the remaining five species of the genus *Listeria* using DNA-arrays (Doumith et al., 2004a). Again, the distribution of surface-protein encoding genes was very heterogeneous. However, each sub-group within the species *L. monocytogenes* was characterized by the presence of specific surface protein-coding genes and only a small group is consistently present in all the *L. monocytogenes* isolates tested. For instance, differences among genes encoding phosphotransferase system (PTS) components or regulatory proteins were much less pronounced, suggesting that they account less for intra- or inter-species differences (Doumith et al., 2004a). These results further provide an explanation why previous studies have found an association between various characteristics of *L. monocytogenes* and serovars, leading to the def-

inition of three lineages within the species *L. monocytogenes*, which are correlated with serovars, suggesting that this association is due to an evolutionary differentiation.

Analysis of the hybridization profiles of different strains revealed distinct patterns of gene presence and absence in different subgroups of *L. monocytogenes* and also allowed identification of 30 *L. monocytogenes*-specific and several serovar-specific marker genes (Doumith et al., 2004a). Based on these results, four serovar-specific marker genes were selected and exploited to design a multiplex PCR, allowing the differentiation of the major *Listeria monocytogenes* serovars (Doumith et al., 2004b). These patterns and markers should further prove to be powerful tools for the rapid tracing of listeriosis outbreaks by PCR for instance, but they also provide a basis for the functional study of virulence differences between *L. monocytogenes* strains. These marker genes and the specific primers are available at Website of Genomic of Microbial Pathogens Unit at Institut Pasteur (http://www.pasteur.fr/recherche/unites/gmp/sitegmp/biodiversitylist. html).

A similar approach using a shotgun microarray and DNA-DNA hybridization corroborated these results by identifying genes specific for *L. monocytogenes* serovar 1/2a as compared to *L. monocytogenes* serovar 4b and 1/2b strains (Zhang et al., 2003). Based on *prf*A virulence gene cluster sequences from 113 *L. monocytogenes* isolates, the presence of three evolutionary lineages among the species *L. monocytogenes* was confirmed and it was shown that the human epidemic associated serotype 4b is prevalent among strains from lineage 1 and lineage 3 (Ward et al., 2004). These results also allowed to develop a PCR-based test for lineage identification.

These different genomic approaches applied to the genus *Listeria* provide for the first time a global view and a more complete knowledge of the gene distribution and the genetic content present in the gene-pool of the genus *Listeria*. This information represents a fundamental basis for functional studies to better understand phenotypic and virulence differences between *L. monocytogenes* strains.

Unsolved Questions and Concluding Remarks

In nearly two decades, *Listeria* has become one of the best-documented intracellular bacteria. Our knowledge of the bacterial factors contributing to infection is increasing daily. Yet understanding the function of the many factors encoded by the genome, involved or not in virulence, will require years of work. When are they expressed, to which regulators are they subjected, when are they active? What is the function of the intergenic regions? Are there some small RNAs involved in virulence? All these questions will require the help of system biology and large-scale genomic analysis.

Several groups are also now addressing biodiversity issues. It is clear that we do not have yet an answer to the question of why some strains are more epidemic than others. However, this information should be available soon, and genes and factors absolutely required for human infection, in addition to the well-established virulence markers LLO and ActA, should be identified soon and fully characterized. Information will also come from large epidemiological studies such as those showing that a complete and functional internalin is as critical as LLO for pathogenesis in humans (Jacquet et al., 2004; Rousseaux, 2004). More interestingly, all serovar 4b strains have a functional internalin, which is not the case for strains of other serovars (Jacquet et al., 2004).

A point that remains unclear is what the infective dose for humans? This is unknown and obviously depends on many individual factors and in particular on the immune status of the host. While ongoing research on adaptive immunity to *Listeria* infections is highly documented (Lara-Tejero and Pamer, 2004), efforts to understand the innate response to *Listeria* are now a priority.

Progress was accomplished to understand how *Listeria* cross barriers. We now know that internalin is used to cross both the intestinal and placental barriers. How does *Listeria* cross the blood brain barrier? There are arguments to predict that internalin may also be used, but the ad hoc animal model is not yet available.

Listeria is one of the "stars" in cellular microbiology (Cossart and Sansonetti, 2004). Its behavior, when in contact with the cell or when spreading intra- and intercellularly, is one of the most sophisticated bacterial behaviors. Many cellular factors contributing to infection have been identified. It is clear that what is lacking now is the spatiotemporal description of all these events at the cellular level, as well as in vivo. All the new in vivo imaging techniques are there. We just need to use them!

In conclusion, it is good that this chapter can be electronically corrected. We are at a period where information is constantly changing, and we still have a lot to learn by studying this amazing organism.

CHAPTER 1.2.12

The Genus *Brochothrix*

ERKO STACKEBRANDT AND DOROTHY JONES

The genus *Brochothrix* contains Gram-positive, nonsporeforming, nonmotile, catalase-positive, facultatively anaerobic, regular, rod-shaped bacteria that show characteristic changes in cell morphology during growth. The genus was proposed by Sneath and Jones (1976) for some meat spoilage organisms, previously designated "*Microbacterium thermosphactum*" (McLean and Sulzbacher, 1953). The genus *Brochothrix* contains the type species *B. thermosphacta* (see Sneath and Jones, 1986) and *B. campestris* Talon et al. (1988), described for isolates from soil and grass. As most of the scientific interests have focused on *B. thermosphacta* because of its association with off-odor development in meats, especially in prepacked products held at refrigeration temperatures, most of the information on the genus is consequently derived from studies on this species. There is no evidence that any *Brochothrix* strain is pathogenic to humans or animals. Neither species has been exploited in industrial processes.

The type strain of *B. thermosphacta* is ATCC [{www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=11509}{11509}]^T (DSM 20171^T) and that of *B. campestris* is CIP [{www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=10290}{10290}]^T = S$_3$^{T} (DSM 4712^T).

Phylogeny and Classification

The bacteria were first isolated and described by Sulzbacher and McLean (1951) during studies on pork sausage meat and were later allocated to the genus *Microbacterium* as a new species, *M. thermosphactum* (McLean and Sulzbacher, 1953). Their classification in the genus *Microbacterium* was due largely to the then poor circumscription of that genus (see Keddie and Jones, 1981). McLean and Sulzbacher (1953) noted the marked difference in cell morphology between *M. thermosphactum* and *M. lacticum*, the type species of the genus, and also commented on the close physiological resemblance between *M.*

thermosphactum and the lactobacilli. However, at that time, both *Microbacterium* and *Lactobacillus* were classified in the family Lactobacteriaceae, and the main distinction between the two genera was catalase production (Breed et al., 1948), therefore, McLean and Sulzbacher (1953) assigned their catalase-positive isolates to the genus *Microbacterium*.

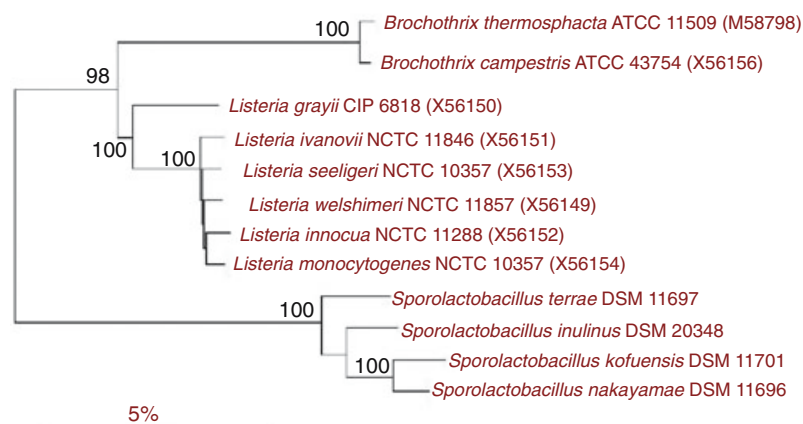
Later workers confirmed and augmented the differences between *M. thermosphactum* and *M. lacticum*, not only in cell morphology (Davidson et al., 1968b; Jones, 1975) but also in enzymology and protein profiles (Robinson, 1966; Collins-Thompson et al., 1972), in peptidoglycan structure (Schleifer, 1970; Schleifer and Kandler, 1972), and in DNA base composition (Collins-Thompson et al., 1972). In addition, numerical taxonomic studies showed that *M. thermosphactum* strains formed a relatively homogeneous taxon (intra-group similarity greater than 85%) quite distinct from *M. lacticum* (Davis and Newton, 1969a; Davis et al., 1969b; Jones, 1975; Wilkinson and Jones, 1977). The same studies indicated that the closest associates of *M. thermosphactum* were the genera *Listeria* and *Lactobacillus*, and in one study, *Kurthia* (Davis and Newton, 1969a). In none of the studies, however, were the similarities close enough to justify the inclusion of *M. thermosphactum* as a new species in any of these genera. Consequently, Sneath and Jones (1976) concluded that *M. thermosphactum* strains were sufficiently distinct from other Gram-positive bacteria to merit a separate genus and proposed that they be reclassified in a new genus *Brochothrix* as *B. thermosphacta*. These authors were aware that the taxonomic relatedness of *Brochothrix* to other Gram-positive bacteria at the suprageneric level was problematic. After evaluating all the data then available, including the presence of catalase and cytochromes in *B. thermosphacta* (Davidson and Hartree, 1968a; Davidson et al., 1968b) and the reported difference in fatty acid composition between *Brochothrix* and *Lactobacillus* (Shaw and Stead, 1970), they tentatively placed *Brochothrix* in the family Lactobacillaceae (Bucha-


Fig. 1. Dendrogram of 16S rRNA gene similarities (De Soete, 1983) between type strains of species of the genera *Brochothrix*, *Listeria* and *Sporolactobacillus*. Numbers indicate the percentage of bootstrap samplings, derived from 1000 resamplings (Felsenstein, 1993). Bar indicates 5% sequence divergence. Numbers in parentheses are accession numbers of 16S rRNA gene sequences. The sequences of *S. terrae*, *S. kofuensis* and *S. nakayamae* were determined for this revision.

nan and Gibbons, 1974); this family included the genus *Lactobacillus* and three other genera designated as having uncertain affiliation, i.e., *Listeria*, *Erysipelothrix* and *Caryophanon*.

Subsequently, it became apparent that in phenotype, the members of the genus *Brochothrix* more closely resembled those of the genus *Listeria* than those of the genus *Lactobacillus* (see Sneath and Jones, 1986). Both *B. thermosphacta* and *Listeria* spp. possess catalase and cytochromes (Davidson and Hartree, 1968a; Feresu and Jones, 1988). They also contain *meso*-diaminopimelic acid in the cell wall peptidoglycan (Schleifer and Kandler, 1972), possess menaquinones with seven isoprene units (MK-7) as the predominant isoprenoid quinone (Collins et al., 1979; Collins and Jones, 1981; Feresu and Jones, 1988), and contain predominantly methylbranched chain fatty acids (Shaw, 1974; Feresu and Jones, 1988). This close phenotypic similarity between *B. thermosphacta* and *Listeria* spp. was confirmed by the results of the 16S rRNA oligonucleotide sequencing studies of Ludwig et al. (1984). These studies showed that *B. thermosphacta* and *L. monocytogenes* are phylogenetically very closely related and form one of the several sublines within the *Bacillus-Lactobacillus-Streptococcus* cluster of the clostridial subbranch of the Gram-positive eubacteria (Stackebrandt and Woese, 1981; Collins et al., 1991).

The species *B. campestris* was named by Talon et al. (1988) on the basis of numerical taxonomic and DNA hybridization studies of a number of strains of *Brochothrix* spp. isolated from a variety of sources, including grass and soil.

On the basis of analyses of 16 rRNA gene sequences, *Brochothrix thermosphacta* and *B. campestris* are highly related, sharing 99.3% sequence similarity. Their phylogenetic neighbors are members of the genus *Listeria* (92.8–96.6%) and less closely related members of the genus *Sporolactobacillus* (<92% on the basis of
Fig. 2. Diversity of normalized *Eco*RI ribotype patterns found within the two type strains of *Brochothrix* species.

ARB [from Latin arbor, tree] analysis; Ludwig et al., 2004). As depicted in the phylogenetic tree (De Soete, 1983; Fig. 1), the three genera are phylogenetically well separated. The small phylogenetic distance found between the two *Brochothrix* type strains are also seen among some of the *Listeria* type strains, i.e., *L. seeligeri*, *L. welshimeri*, *L. ivanovii*, *L. innocua* and *L. monocytogenes* (>99.1%). The majority of the branching points are supported by high bootstrap values.

As determined by the S1 nuclease method at 60°C, *B. campestris* strains exhibit about 15% DNA similarities to *B. thermosphacta* (Talon et al., 1988), which identifies both strains as sound genomospecies. This is also reflected by the significant difference in the RiboPrint patterns (Fig. 2).

Chemotaxonomy

Other than the presence of *meso*-diaminopimelic acid in the cell wall of *Brochothrix campestris* (Talon et al., 1988) and *B. thermosphacta* (Schleifer, 1970; Schleifer and Kandler, 1972), all the information on chemical composition is based on studies with *B. thermosphacta*. Arabinose and galactose are not present in the cell wall (see

Schleifer and Kandler, 1972), nor are mycolic acids (Minnikin et al., 1978; Feresu and Jones, 1988). The major fatty acid is 12-methyltetradecanoic (*anteiso*-C$_{15:0}$ with substantial amounts of 14-methylhexadecanoic (*anteiso*-C$_{17:0}$) and 13-methyltetradecanoic (*iso*-C$_{15:0}$) acids (Shaw and Stead, 1970; Feresu and Jones, 1988). The major phospholipids are phosphatidylglycerol, diphosphatidylglycerol and phosphatidylethanolamine. The glycolipid fraction contains an acylated glucose and small amounts of a glycosyl diglyceride tentatively identified as dimannosyl diglyceride (Shaw and Stead, 1970; Shaw, 1974). Sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) whole-cell protein profiling has been used to characterize *B. thermosphacta* during monitoring changes in populations in chilled vacuum-packed beef (Sakala et al., 2002)

Brochothrix thermosphacta and *B. campestris* contain several membrane-bound respiratory cytochromes, such as *aa*$_3$, *a*$_3$, *b* and *d* (Gil et al., 1992), but only strains of the former species were subjected to analyses at different growth temperatures. Under moderate aeration, cytochromes *b* and *d* dominate at 30°C, while *aa*$_3$ and *a*$_3$ are the dominating components when grown at 10°C and 15°C. Reduction of the oxygen content in batch cultures lead to an enhancement of cytochrome *d* and a reduction in *a*-type cytochromes. Cytochrome *c* was missing in both species, which otherwise show similar cytochrome compositions when grown at 10°C.

Menaquinones are the sole respiratory quinones; MK-7 is the major component, and MK-6 and MK-5 are minor components (Collins et al., 1979; Collins and Jones, 1981; Feresu and Jones, 1988).

The G+C content of the DNA of *B. thermosphacta* is 36–37 mol% (Collins-Thompson et al., 1972; Collins et al., 1987; Feresu and Jones, 1988) and of *B. campestris*, 38 mol% (Talon et al., 1988).

Characterization

The colonial morphology of *Brochothrix* spp. is not particularly diagnostic. After 24–48 h, the colonies are circular, 0.75–1 mm in diameter, convex with entire margins, and not pigmented. In young cultures of *B. thermosphacta*, two types of colony varying in size and density may be present. These can be so distinct that the culture may appear to be contaminated (see Barlow and Kitchell, 1966). In older cultures of the same species, the edge of the colony breaks up and the center becomes raised to give a "fried egg" appearance. Neither of these two phenomena has been reported for *B. campestris* (Talon et al., 1988). *Brochothrix* spp. are nonhemolytic, but sometimes an area of weak greening is apparent around colonies on blood agar.

Gram-stains on exponential-phase cultures of *B. thermosphacta*, performed on 18–24 h and 2-day cultures grown on nutrient agar such as blood agar base (Columbia or BAB no. 2, Oxoid) or APT medium incubated at 20–25°C, show regular, unbranched rods that occur singly in pairs and short chains and in long, kinked, filamentous-like chains (Fig. 3a) that bend and loop to give characteristic knotted masses. This phenomenon has not yet been reported for *B. campestris*; in this species 24-h cultures are reported to consist of a mixture of long and short rods that usually occur singly or in pairs (Talon et al., 1988). In older cultures of *B. thermosphacta*, the rods give rise to coccoid forms (Fig. 3b) that when subcultured onto a suitable medium develop into rod forms. Both rod and coccal forms are Gram-positive, but a proportion may appear Gram-negative. They are nonmotile and do not form endospores or capsules. Talon et al. (1988) reported that about one-half of the *B. thermosphacta* strains they examined produced slime from sucrose in broth culture.
Fig. 3. *Brochothrix thermosphacta* isolate, grown on blood agar base no. 2 (Oxoid) at 25°C. (a) After 24 h, showing regular rods in chains. (b) After 48 h, showing development of coccoid forms. Bar = 10 μm.

In MRS medium the type strains of *B. thermosphacta* and *B. campestris* produce acid fermentatively from glucose, ribose, fructose, mannose, salicin, maltose, D-cellobiose, mannitol, trehalose and, weakly, from gluconate (R. Pukall, unpublished observation); acid production from *N*-acetylglucosamine has also been reported; they are methyl-red and Voges-Proskauer positive. Esculin is hydrolyzed. Exogenous citrate and urea are not utilized. Indole and H$_2$S are not produced, nitrate is not reduced, gelatin is not liquefied, and arginine is not hydrolyzed (McLean and Sulzbacher, 1953; Sneath and Jones, 1976; Wilkinson and Jones, 1977; Talon et al., 1988).

With use of the API ZYM test system (API System, La Balme des Grottes, France), both species are reported to produce the following arylamidases: phenylalanine, histidine, glycyl-phenylalanine, seryl-tyrosine, glutamate, tryptophan, and histidyl-L-phenylalanine (Talon et al., 1988).

In the API esterase tests, Talon et al. (1988) noted that all five strains of *B. campestris*, but only 12 of 165 strains of *B. thermosphacta* tested, hydrolyzed naphthylbutyrate, naphthylvalerate, naphthylcaproate, naphthylcaprylate, naphthylnonanoate and naphthylcaprate.

According to the BIOLOG GP2 substrate panel (R. Pukall, unpublished observation), *B. thermosphacta* DSM [{www.ncbi.nlm.nih.gov/entrez /query.fcgi?db=nucleotide=search=20171} {20171}]^T and *B. campestris* DSM [{www.ncbi.nlm.nih.gov/entrez/query.fcgi? db=nucleotide=search=4712}{4712}]^T utilize dextrin, N-acetyl-D-glucosamine, N-acetyl-D-mannosamine, amygdalin, arbutin, D-cellobiose, D-fructose, gentiobiose, D-gluconic acid, μ-D-glucose, *m*-inositol, maltose, maltotriose, D-mannitol, D-mannose, pyruvic acid, palatinose, D-trehalose, thymidine, β-methyl-D-glucoside, D-ribose, salicin, glycerol, inosine and uridine. Neither type strain utilizes α-cyclodextrin, β-cyclodextrin, glycogen, inulin, mannan, Tween 40, Tween 80, L-arabinose, D-arabitol, L-fucose, D-galactose, D-galacturonic acid, α-D-lactose, lactulose, D-melizitose, D-melibiose, D-tagatose, xylitol, D-xylose, acetic acid, α- and β-hydroxy-butyric acid, γ-hydroxy-butyric acid, p-hydroxy-phenyl acetic acid, α-keto-glutaric acid, lactamide, D-lactic acid methyl ester, D- and L-malic acid, mono-methyl succinate, propionic acid, succinamic acid, succinic acid, N-acetyl-L-glutamic acid, L-alaninamide, D- and L- alanine, L-alanyl-glycine, L-asparagine, L-glutamic acid, glycyl-L-glutamic acid, L-pyroglutamic acid, α- and β-methyl-D-galactoside, 3-methyl-glucose, α-methyl-D-glucoside, α-methyl-D-mannoside, D-raffinose, sedoheptulosan, D-sorbitol, stachyose, L-serine, putrescine, 2,3-butandiol, 2'deoxy adenosine, adenosine-5'monophosphate, thymidine-5'monophosphate, uridine-5'monophosphate, fructose-6-phosphate, glucose-1-phosphate, and glucose 6-phosphate.

Both species are susceptible to a wide range of antibiotics. Using antibiotic disks on Mueller-Hinton agar, Talon et al. (1988) reported all strains of *B. thermosphacta* (104 tested) and *B. campestris* (5 tested) were sensitive to novobiocin, tetracycline (except for three strains of *B. thermosphacta*), amikacin, tobramycin, gentamicin, and ampicillin and were resistant to oxacillin, nalidixic acid, and colistin (except the type strain of both species and one other strain of *B. campestris*). A wider range of antibiotics was tested with *B. thermosphacta* (15 strains) on nutrient agar medium by Feresu and Jones (1988).

Further diagnostic information on both species is given in Table 1. Both type strains are suitable reference strains, but it should be noted that *B. campestris* grows with 8% NaCl if incubated for 6 days (Talon et al., 1988).

Sneath and Jones (1976) reported that *B. thermosphacta* does not produce deoxyribonuclease, but later studies have detected both deoxyribonuclease and ribonuclease activity in strains of this species (Wilkinson and Jones, 1977; Feresu and Jones, 1988).

The results of many of the conventional tests can be influenced markedly by the media and methods used. Differences in methodology probably account for some of the discrepancies noted in the literature. Media and methods such as those used by Talon et al. (1988) and Wilkinson and Jones (1977) are suitable for most tests, and incubation should be at 20–25°C.

Differentiation of Brochothrix species

The most useful phenotypic characters for differentiating the two species are growth in the presence of 8 and 10% NaCl, growth on BM medium (Wilkinson and Jones, 1977) containing 0.05% potassium tellurite, hippurate hydrolysis, and production of acid from rhamnose (Table 1).

Molecular Identification

Affiliation of a yet unassigned isolate to the genus is unambiguously done by sequence analysis of the 16S rRNA gene when sequence differences between the type strains of the two species are significant (Stackebrandt and Goebel, 1994). The difference between the type strains of *Brochothrix* is 0.7% only, making it difficult to taxonomically place a new strain. A

Table 1. Additional and differential features of *Brochothrix* spp.

Features	B. thermosphacta	B. campestris
Growth with		
NaCl, 8% (2 days)	+	−
NaCl, 10% (2–7 days)	d	−
Growth with and reduction of potassium tellurite, 0.05%	+	−
Reduction of tetrazolium, 0.01%	d	+
Slime produced from sucrose	d	−
Resistance to furadoine	d	−
Hydrolysis of:		
Hippurate	−	+
Cellulose	+	ND
Tyrosine	−	ND
Xanthine	−	ND
Production of		
Phosphatase	+	ND
Sulfatase	−	ND
Utilization according to BIOLOG GP2		
Turanose	+	−
α-Keto valeric acid	+	−
L-Lactic acid	+	−
Rhamnose	−	+
Saccharose	+	−
Adenosine	+	−
D,L-α-glycerol-phosphate	+	−
Acid from		
Amygdalin	+	+
Arbutin	d	+
Dulcitol	+	ND
Gentobiose	+	d

Tagatose	+	d
Xylose	d	ND

Symbols and abbreviations: +, 90–100% of strains positive; −, 0–10% of strains negative; d, 11–89% of strains positive; ND, no data.

[a]Type strain negative in MRS. (de Man-Rogosa-Sharpe).

strain branching deeper than the bifurcation of the two type strains but closer to these than to members of the nearest neighboring genus must be taxonomically evaluated by means of genus-specific properties to decide whether it belongs to *Brochothrix* or whether it forms the nucleus of a novel genus.

Riboprints are available for the two type strains (Fig. 2), but patterns from more strains of both species are needed to evaluate the homogeneity of rrn cistron cleaving patterns of these taxa. Oligonucleotide primers targeting variable regions within the 16rRNA gene have been designed for the rapid detection of *Brochothrix*

spp. (Grant et al., 1993). When combined with the capture of *Brochothrix* cells using a lectin immobilized on magnetic beads the polymerase chain reaction (PCR) assay targeting DNA from released cells was sufficiently sensitive to detect as low as about 100 colony forming units (CFU) per gram of chopped fresh chicken meat.

A rabbit polyclonal antibody-linked probe allowed detection of 76% of 800 presumptive *B. thermosphacta* isolates from British fresh sausages. Of collection strains investigated, only the type strain NCTC [{www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=10822}{10822}][T] did not react, while one strain each of

Kurthia zopfii and *Staphylococcus aureus* reacted positively, demonstrating the lack of specificity (Stringer et al., 1995). Other detection methods (such as denaturing gradient gel electrophoresis [DGGE; Cocolin et al., 2001], oligonucleotide probes [Kim et al., 1991], and low molecular weight RNA profiles) were able to differentiate lactobacilli and *Listeria* spp. from *Brochothrix* spp. and other meat spoilage organisms (Collins-Thompson et al., 1991).

Differentiation of Brochothrix from Phylogenetically Neighboring Genera

Phenotypic identification of new isolates as *Brochothrix* spp. requires examination of cellular morphology and staining reactions, the maximum growth temperature, and relationships to oxygen and catalase production together with a number of conventional taxonomic tests, such as the ability to produce acid from various sugars. The chemical composition of the organisms also aids the identification of *Brochothrix* spp., but performing the relevant analyses for routine identification is not usually necessary. Features that differentiate the genus from other Grampositive, nonsporeforming, rod-shaped bacteria are listed in Table 2.

Brochothrix spp. are readily distinguishable from the morphologically similar members of the genus *Kurthia* by examining the oxygen requirements. *Brochothrix* is facultatively anaerobic whereas *Kurthia* is strictly aerobic. In addition, *Brochothrix* spp. produce acid from a wide variety of sugars. Most strains of *Kurthia* are highly motile.

The inability of *Brochothrix* spp. to grow at 35°C distinguishes them from members of the genera *Carnobacterium*, *Erysipelothrix*, *Lactobacillus* and *Listeria*. Although facultatively anaerobic, *Brochothrix* spp. grow best aerobically. This feature, together with their ability to grow on unsupplemented nutrient agar, serves to distinguish *Brochothrix* spp. from members of the genera *Erysipelothrix* and *Lactobacillus* but not from *Carnobacterium* and *Listeria*.

The production of catalase distinguishes *Brochothrix* spp. from the genera *Carnobacterium*, *Erysipelothrix*, and the vast majority of *Lactobacillus* spp., but not from *Listeria*. But as noted previously, care must be taken in examining *Brochothrix* for catalase because its production depends on both the growth medium and the incubation temperature. Growth on APT medium, BAB no. 2 or a similar medium for 24–48 h at 20–25°C is recommended; negative results are very frequently obtained if the bacteria are incubated at 30°C. Although catalase production by *Listeria* spp. is also dependent on the composition of the growth medium (Jones, 1975), all strains of *Listeria* are unequivocally catalase-positive at 35°C if the growth medium is suitable, whereas *Brochothrix* spp. do not grow at this temperature.

The genera *Brochothrix* and *Listeria* share many common characters. Members of both genera are facultatively anaerobic but grow better aerobically; produce acid from a variety of sugars; produce catalase, cytochromes, and menaquinones; possess a cell wall peptidoglycan with *meso*-diaminopimelic acid as the diamino acid; have similar polar lipid and fatty acid profiles and similar G+C content (Table 1). Members of neither genus grow on acetate medium and only poorly on MRS (De Man et al., 1960) medium. In contrast to the comment by Jones (1992), *B. thermosphacta* and *B. campestris* do grow on MRS medium, though the type strain of the latter species grows more slowly. Members of *Listeria* and *Brochothrix* may be distinguished by their morphology, by growth temperature, by motility, and also serologically.

Table 2. Features most useful in differentiating *Brochothrix* from morphologically similar genera.

	Brochothrix	*Listeria*	*Carnobacterium*	*Lactobacillus*	*Erysipelothrix*	*Kurthia*
Growth at 35°C	−	+	+	+	+	+
Motility	−	+	−	−	−	+
Catalase	+	+	−	−	−	+
Facultatively anaerobic	+	+	+	+	+	−
Acid from glucose	+	+	+	+	+	−
H$_2$S production	−	−	−	−	+	−
Major peptidoglycan di-amino acid	*meso*-A$_2$pm	*meso*-A$_2$pm	*meso*-A$_2$pm	Lysine or *meso*-A$_2$pm or ornithine	L-Lysine	L-Lysine
Major menaquinone	MK-7	MK-7	−	−	−	MK-7
Major fatty acid types	S, A, I	S, A, I	S, U, (C)	S, U, (C)	S, A, I, U	S, A, I
G+C mol%	36–38	36–42	33–37	32–53	36–40	36–38

Symbols and abbreviations: +, present; , absent; MK-7, menaquinones with seven isoprene units; S, straight chain saturated; A, *anteiso*-methyl branched; I, *iso*-methyl-branched; U, monounsaturated; and (C), cyclopropane ring fatty acids may be present.

Colonies of the genus *Brochothrix* do not show the blue-green coloration exhibited by *Listeria* spp. when viewed by obliquely transmitted white light. The inability of *Brochothrix* spp. to grow at 35°C and their lack of motility also distinguishes them from the genus *Listeria*. No serological crossreactions have been demonstrated between *B. thermosphacta* and species of the genus *Listeria*.

General Properties

Metabolism and Nutritional Requirements

Brochothrix spp. are aerobic, oxidase negative, catalase positive and facultatively anaerobic (Sneath and Jones, 1986; Talon et al., 1988), but better growth is achieved by *B. thermosphacta* aerobically (see Hitchener et al., 1979 and Gardner, 1981); no such information is yet available for *B. campestris*.

Brochothrix thermosphacta possesses enzymes for both the hexose-monophosphate and Embden-Meyerhof (glycolysis) pathways of glucose catabolism as well as a number of enzymes involved in pyruvate metabolism (Collins-Thompson et al., 1972; Grau, 1983). Fermentative metabolism of glucose always results in the production of L(+) lactic acid, but other end products depend on the growth conditions. McLean and Sulzbacher (1953) found only L(+) lactic acid present in detectable quantities. Davidson et al. (1968b) detected small amounts of acetic and propionic acids in addition to L(+) lactic acid. Hitchener et al. (1979) found that in glucose-limited continuous culture under anaerobic conditions, L-lactate and ethanol were produced in the approximate ratio of $3:1$. The studies of Grau (1983) showed the major end products of anaerobic glucose fermentation to be primarily L-lactate, acetate, formate and ethanol, but that the ratios of these end products varied with conditions. Both the presence of acetate and formate and a pH below 6 increased L-lactate production from glucose. Of interest in this context is that the growth of *B. thermosphacta* is inhibited at a pH below 5 (Brownlie, 1966). Although McLean and Sulzbacher (1953) reported detectable CO_2 production (in Eldridge fermentation tubes), this has not been confirmed in any subsequent studies, but Hitchener et al. (1979) speculated that CO_2 was a likely end product in their studies on glucose-limited cultures.

The major end products of aerobic metabolism of glucose by *B. thermosphacta* growing on tryptone-based medium, on a minimal defined medium, or on meat are acetoin and acetic, isobutyric, isovaleric (3-methylbutyric), and 2-methylbutyric acids (Dainty and Hibbard, 1980; Dainty and Hibbard, 1983). In the minimal defined medium, glucose is believed to be the source of all the end products (Dainty and Hibbard, 1983); whereas in the complex medium and meat, only acetoin and acetic acid are derived from glucose; and isobutyric, isovaleric, and 2-methylbutyric acids are produced from valine, leucine and isoleucine, respectively (Dainty and Hibbard, 1980; Dainty and Hibbard, 1983). These compounds, or their derivatives, produce the sweet, sickly, malty odors that characterize the growth of *B. thermosphacta* (Dainty et al., 1985). The studies of Grau (1988) indicate that the substrates used by *B. thermosphacta* growing aerobically on meat include glucose, ribose, glycerol, glycerol-3-phosphate, and inosine; of these substrates, only glucose and ribose are metabolized during anaerobic growth.

In cultures of *B. thermosphacta* grown on a tryptone-based medium, enzymes of the tricarboxylic acid (TCA) cycle are almost totally absent (Collins-Thompson et al., 1972). However, Grau (1979) has suggested, on the basis of studies with a defined medium, that the TCA-cycle enzymes may be sufficiently active to provide substrates but not energy for synthesis.

Collins-Thompson et al. (1971) demonstrated the presence of a glycerol ester hydrolase (lipase) in cell suspensions and cell-free extracts of *B. thermosphacta*. The lack of significant lipase activity in supernatant fluids was confirmed by Papon and Talon (1988). This lipase, mostly produced during the logarithmic phase of growth is active on tripropionin, tricaproin, tricaprylin and trilaurin but not on tripalmitin. Because the temperature optimum of the lipase is 35–37°C with little or no activity below 20°C, this enzyme is unlikely to be important in meat stored at refrigeration temperatures; optimal temperatures for growth and lipase production was 24°C. The report that *B. thermosphacta* cultures attack tributyrin (Sutherland et al., 1975) has not been subsequently confirmed (Davis et al., 1969b; Patterson and Gibbs, 1978), and Papon and Talon (1988) could even demonstrate that growth and lipase production is inhibited by tributyrin.

Brochothrix thermosphacta requires cysteine, α-lipoate, nicotinate, pantothenate, *p*-aminobenzoate, biotin, and thiamine for growth (Grau, 1979). Thiamine can fulfil most, but not all, of the yeast extract requirements (Macaskie et al., 1981).

The production of cytochromes and catalase by *B. thermosphacta* depends on both the composition of the growth medium and the temperature of incubation (Davidson and Hartree, 1968a; Davidson et al., 1968b). The latter authors noted that *B. thermosphacta* strains grown on

APT medium (Baltimore Biological Laboratories [BBL], Cockeysville, MD; Evans and Niven, 1951) incubated at 20°C were always catalase-positive but that weak or negative reactions were obtained on HIA (heart infusion agar) medium (Difco, Detroit, MI) incubated at the same temperature The same authors reported that negative results were frequently obtained if the bacteria were grown on either medium at 30°C. Davidson and Hartree (1968a) reported the same effects of growth medium and incubation temperature on the quantitative cytochrome content of the organism. On APT medium incubated at 20°C, *B. thermosphacta* contains cytochromes baa_3 (Davidson and Hartree, 1968a). The temperature effect is difficult to explain; although not the optimum temperature for growth, *B. thermosphacta* grows well at 30°C. The effect of the composition of the culture medium may be related to the iron concentration. Davidson et al. (1968b) noted that APT medium contains added iron (8.0 µg/ml), and more recently both Grau (1979) and Thomson and Collins-Thompson (1986) have noted a high ferric iron requirement for the aerobic growth of *B. thermosphacta* in defined media. More recently it was shown that manganese can partially replace the iron requirement of *B. thermosphacta* under iron-limiting conditions (Thomson and Collins-Thompson, 1988).

Temperature and pH

There is general agreement that the temperature limits of growth are between 0 and 30°C (see Sneath and Jones [1976], Gardner [1981], and Talon et al. [1988]). Limited growth of *Brochothrix thermosphacta* was noted at 35°C and one strain was reported to grow at 37°C and 45°C (Gardner, 1981), but growth above 30°C has been rarely found. *Brochothrix campestris* does not grow at 37°C (Talon et al., 1988). The optimum temperature for growth is 20–25°C (see Gardner, 1981). The heat resistance of *B. thermosphacta* has received much attention because of its former classification in the genus *Microbacterium*, members of which are thermoduric. All workers agree that *B. thermosphacta* does not survive heating at 63°C for 5 min (see Gardner [1981] and Sneath and Jones [1986]).

The optimum pH for growth of *B. thermosphacta* is pH 7.0, but growth occurs within the range pH 5–9 (Brownlie, 1966).

Inhibitory Substances

The ability of *Brochothrix thermosphacta* to grow in the presence of NaCl has been examined by many workers (see Gardner, 1981). All strains grow at 6.5% NaCl and the majority can grow at NaCl concentrations up to 10% (Wilkinson and Jones, 1977; Talon et al., 1988). *Brochothrix campestris* strains do not grow in media with 8% or 10% NaCl and although there is no published information to indicate growth at 6.5% NaCl, circumstantial evidence indicates that *B. campestris* grows with 6.5% NaCl.

Growth of *B. thermosphacta* is inhibited by nitrite, but the degree of inhibition is related to the pH of the medium and incubation temperature (Brownlie, 1966); low pH, low temperature, and high nitrite increase the inhibitory effect. The species does not appear to have a nitrite reductase system (Collins-Thompson and Rodriguez-Lopez, 1980). Dainty and Meredith (1972) found that 200 parts per million (ppm) of nitrite at pH 5.5 stops RNA, DNA, and protein synthesis in *B. thermosphacta* but has no effect on membrane permeability. An interesting study on the combined effects of NaCl, $NaNO_2$, temperature, and pH on the growth of *B. thermosphacta* in broth cultures was done by Roberts et al. (1979). Also, sodium lactate has been used effectively against *B. thermosphacta* (reduction by 4 logs as compared to the control after 14 days; Lemay et al., 2002). Microgard 100, Microgard 300, Alta 2002, and Perlac 1902 had no significant effect on tests using an acidified chicken meat model.

In the United Kingdom, sulfur dioxide is permitted in sausage meat and *B. thermosphacta* tolerates SO_2 up to 500 ppm under both aerobic and anaerobic conditions (Dowdell and Board, 1971).

The studies of Macaskie (1982) indicate that in liquid culture palmitic acid is inhibitory to the growth of *B. thermosphacta*.

In plate overlay assays, triclosan-incorporated plastic (TIP) inhibited, among other Gram-positive and Gram-negative organisms, also *Brochothrix thermosphacta*. When TIP was used to cover irradiated, lean beef surfaces inoculated with various bacteria, only populations of *B. thermosphacta* were reduced (Cutter, 1999).

Brochothrix thermosphacta became the main species responsible for putrefaction when poultry carcasses were decontaminated with AvGuard (or Assur-Rinse in the United States) trisodium phosphate. This treatment preferentially removed pseudomonads with the consequence that *B. thermosphacta* lacked competition for utilization of substrates; as however, growth rate of *B. thermosphacta* was greater than that of *Listeria monocytogenes*, putrefaction would occur before the emergence of large numbers of the latter species (Salvat et al., 1997).

Brochothrix thermosphacta is more resistant to irradiation than common meat spoilage organisms such as *Pseudomonas* (Ouattara et al., 2002)

but are affected by irradiation doses of 0.5 and 2.0 kilogray (kGy; Savvaidis et al., 2002). The species has been frequently isolated from irradiated meat and poultry (see Gardner, 1981).

Serology

There do not appear to have been any systematic serological studies of *Brochothrix* spp. Wilkinson and Jones (1975) did not detect any serological relationship between *B. thermosphacta* and the genera *Erysipelothrix*, *Kurthia* or *Listeria* with antisera raised against representative strains of all four taxa.

Esterase Isoenzymes

Five different esterase isoenzymes have been detected by gel electrophoresis studies of *Brochothrix thermosphacta*. Different combinations of these enzymes resulted in the detection of seven groups among 26 strains examined. There was no correlation between source of isolation and groups based on esterase patterns (G. A. Gardner, personal communication).

Bacteriophages

Greer (1983) isolated bacteriophages active on *Brochothrix thermosphacta* from aqueous extracts of spoiled beef. Both phage plaque size and plating efficiency increased significantly when the incubation temperature was reduced from 25°C to 1°C. The detection of 14 distinct phage lysotypes led Greer (1983) to suggest that phage typing may provide a rapid method of differentiating *B. thermosphacta* strains.

On the basis of their morphology as determined by electron microscopy, Ackermann et al. (1988) grouped these bacteriophages (and two isolated in France from broth cultures of lysogenic *B. thermosphacta* strains) into three viral species of the Myoviridae (species A19) or Siphoviridae (species NF5 and BL3). The bacteriophage species A19 are interesting because of their similarity to some bacteriophage species of the genera *Bacillus*, *Lactobacillus*, *Staphylococcus* and *Streptococcus*. Surprisingly, none of the bacteriophages resembled those of the genus *Listeria* (Ackermann et al., 1988).

Bacteriophages have been used to control *B. thermosphacta* spoilage of pork adipose tissue. In the presence of 10^5 bacteria per cm^2 tissue disk and an equivalent number of phages, phage numbers increase by 1000-fold while bacterial number decreased by a factor of 100. As a result, off-odors were suppressed during refrigeration, allowing increase of the storage life of the adipose tissue (Greer and Dilts, 2002).

Plasmids

Dodd and Waites (1988) detected plasmids in all strains of *Brochothrix thermosphacta* isolated from sausages containing 450 ppm of sulfite, but not in the type strain (NCTC [{www.ncbi.nlm.nih.gov /entrez/query.fcgi?db=nucleotide =search=10082}{10082}]). The plasmids ranged in size from 1600 to 43,000 and plasmid numbers varied from 1 to 8 per cell. Comparison of the plasmid profiles of the isolates showed that fewer profiles were present amongst the strains isolated from sausages stored for various periods at 4°C than were present amongst strains isolated from the same sausages on the day of manufacture. Dodd and Waites (1988) interpreted these observations as indicating that only some strains of *B. thermosphacta* were able to survive the conditions of storage.

Bacteriocins

Brochocin C, produced by *Brochothrix campestris*, was discovered and classified (Siragusa and Cutter, 1993) as a bacteriocin active against *B. thermosphacta*, *Listeria monocytogenes* and several strains of *Carnobacterium*, *Kurthia*, *Lactobacillus*, *Pediococcus*, *Streptococcus* and even endospores of *Clostridium* and *Bacillus* spp. (McCormick et al., 1998). In its activity spectrum, brochocin C is similar to the lantibiotic nisin A. Brochocin C is a nonlantibiotic class II bacteriocin, consisting of two peptides (BrcA and BrcB) that are the result of a Gly-Gly cleavage of a prepeptide. Both peptides are necessary for activity (Garneau et al., 2003). Immunity against the bacteriocin is due to an immunity protein, encoded downstream of the *brcB* gene. In Gram-negative bacteria, the outer membrane acts as a barrier against nisin and brochocin (Gao et al., 1999).

Brochothrix spp, like other Gram-positive relatives, are inhibited by bacteriocins such as the thermosensitive peptide produced by *Streptococcus thermophilus* 580 (Mathot et al., 2003), salivaricin B, excreted by *Lactobacillus salivarius* M7, acidocin B from *Lactobacillus acidophilus* M46 (Ten Brink et al., 1994; Leer et al., 1995), and nisin. Nisin is widely studied as an agent controlling the growth of meat spoilage bacteria (Gill and Holley, 2000; Nattress et al., 2001; Nattress and Baker, 2003). As compared to free nisin, calcium-alginate-bound nisin as well as the meat binding system Fibrimex® plus nisin are more effective inhibitors of *B. thermosphacta* (Cutter and Siragusa, 1996; Cutter and Siragusa, 1998). Nisin-incorporated polymers (polyethylene and polyethylene oxide) also reduce *B. thermosphacta* in experimentally surface-inoculated vacuum packed beef (Cutter et al., 2001).

Habitats

The natural habitat of *Brochothrix* spp. is not known with certainty. This is mainly because for many years after the first reported isolation of the type species, *B. thermosphacta*, from finished pork sausage and its subsequent incrimination as an important psychrotrophic spoilage organism of meat and meat products, most investigators concentrated only on these materials (see Gardner [1981] and Keddie and Jones [1981]). During studies on the development of a selective medium for the enumeration of *B. thermosphacta* from meat sources, Gardner (1966) isolated the organism from soil and feces, but in low numbers. More recently *B. thermosphacta* has been isolated from a variety of sources that include fish and fish products, frozen foods, milk, and cream (see Gardner [1981] and Sneath and Jones [1986]). Both *B. thermosphacta* and *B. campestris* have also been isolated from soil and grass (Talon et al., 1988). To date, soil and grass are the only described habitats of *B. campestris*, but it is possible that this species has been misidentified as *B. thermosphacta* in the past. From the information available it seems probable that *Brochothrix* spp. are widely distributed in the environment and become a prominent part of the flora in habitats that selectively favor their growth.

The turbidimetric method of counting *Brochothrix thermosphacta* correlated well with bacterial numbers determined by plate counts, flow cytometry, and manual counts (by microscope) over a limited range of 10^7–10^9 cells/ml. Flow cytometry and manual counts gave a linear relationship over a wider range of 10^5–10^9 cells/ml. Passage of *B. thermosphacta* cells through the flow cytometer resulted in the breakage of chains into single cells which makes this technique attractive for bacterial enumeration (Rattanasomboon et al., 1999).

Meat and Meat Products

Since *Brochothrix thermosphacta* was first isolated from pork trimmings and finished sausage (Sulzbacher and McLean, 1951), it has been isolated regularly from the same sources and from a variety of meats (including poultry) and meat products (see the detailed list of references in Jones, 1991). An excellent, comprehensive review of the isolation of *B. thermosphacta* from, and its ecological association with, beef, lamb and pork, and cured and uncured products made from these meats and poultry meat was done by Gardner (1981). Most of the recent reports deal with verification of *B. thermosphacta* in meat subjected to different preservation regimes, e.g.,

Gill and Bryant (1992), Prieto et al. (1993), Kakouri and Nychas (1994), Borch et al. (1996), Jimenez et al. (1997), Lopez-Caballero et al. (1999), Samelis and Georgiadou (2000), Silv et al. (2000), Gill and Badoni (2002), Gonzalez-Rodriguez et al. (2002), Bohaychuk and Greer (2003), Susiluoto et al. (2003), and Greer et al. (2004).

Brochothrix thermosphacta is especially important as a spoilage organism in prepacked meats and meat products stored at chill temperatures (see Gardner, 1981). The conditions prevailing during such storage selectively favor its growth (Gardner et al., 1967). *Brochothrix* spp. grow at temperatures as low as 0°C and under conditions of O_2 depletion and increased CO_2 concentration (Pin et al., 2002). Other factors that inhibit or enhance the growth of *B. thermosphacta* during the storage of particular meats (including poultry) and meat products are reviewed by Gardner (1981). These include the chemical and physical properties of the various meats; temperature of storage; composition of gaseous environment; pH; presence of NaCl, $NaNO_2$ or SO_2; previous heat treatment; and interactions with other spoilage bacteria (see also Nychas et al., 1988).

Unlike proteolytic spoilage bacteria (e.g., *Pseudomonas*), *B. thermosphacta* is usually found only on the meat surface (Gill and Penney, 1977), and in prepacked meats, it grows well at the meat-plastic film interface (Ingram and Dainty, 1971). However, Fournaud et al. (1980) demonstrated histologically that meat spoilage bacteria, including *B. thermosphacta*, can penetrate the deep muscle mass by following the perimysium or endomysium connective tissue. Of interest is their observation that the flora of deep muscle tissue stored aerobically was dominated by *B. thermosphacta* whereas that of vacuum-packed meat was dominated by *Lactobacillus*.

Contamination of meats almost certainly occurs during slaughter and postslaughter procedures. *Brochothrix thermosphacta* has been isolated from the hides of cattle (Mulder, 1978; Newton et al., 1978); cattle hair, rumen contents, floors and equipment in slaughter halls (Patterson and Gibbs, 1978; Talon et al., 1988); sheep wool and sheep feces (Talon et al., 1988); equipment and tables used in the preparation of sausage (McLean and Sulzbacher, 1953); and cooked rind and fat emulsions added to pork sausages (Gardner, 1981).

Fish and Fish Products

In the last 10 years, *Brochothrix thermosphacta* has been isolated from fish sources, but it does not appear to be as economically important; nor does it comprise as large a proportion of the

microflora as it does in meat. Nickelson et al. (1980) isolated *B. thermosphacta* at all stages in the production (whole fish, scaled, beheaded, eviscerated, and minced flesh) of minced fish flesh from nontraditional finfish caught in the Gulf of Mexico, but the proportion of the total microflora rarely exceeded 5%. Lannelongue et al. (1982) isolated *B. thermosphacta* from stored finfish fillets packaged in a CO_2 atmosphere. Again the numbers recovered as a proportion of the total microbial population were small. The species has also been isolated from fish fingers, smoked whiting, frozen coley, and frozen cod (Gardner, 1981). Little information on *Brochothrix* detected on fish has been published in the past 10 years. Investigation of vacuum-packed cold-smoked salmon and trout has indicated a low number of *Brochothrix* spp. (Gonzalez-Rodriguez et al., 2002). These organisms have also been detected in the Mediterranean boque (*Boops boops*) but were found to constitute a population with a density of 2–3 $\log_{10}$ CFU g^{-1}, less than that of pseudomonads (Koutsoumanis and Nychas, 1999).

Brochothrix campestris has not been observed in fish or fish products but prior to the study of Talon et al. (1988), misidentification could have occurred. Talon et al. (1988) did not examine these sources.

Other Sources

Brochothrix thermosphacta has been isolated from soil, grass, hay, and feces but apparently only in low numbers and with the use of selective media. There have also been reports of the isolation of the species from a variety of foods such as frozen peas, frozen runner beans, prepackaged tomato salad, milk, cream, and cottage cheese (Gardner, 1981).

As noted earlier, the only currently known habitats of *B. campestris* are grass and soil (Talon et al., 1988). Inspection of the numbers of isolates of *B. thermosphacta* and *B. campestris* from grass and soil studied by these workers does not indicate that *B. campestris* forms a larger proportion of the microflora of these habitats than does *B. thermosphacta*; no other indication of the relative proportions of the two species in grass and soil samples is reported (Talon et al., 1988).

Neither *B. thermosphacta* nor *B. campestris* appear to have been isolated from clinical sources.

Isolation of Brochothrix

Until recently the methods described for the isolation of *Brochothrix* have been mainly concerned with the isolation of *B. thermosphacta*

from meats and meat products. *Brochothrix campestris* grows equally well on the same media. Neither species grows on the acetate medium devised by Rogosa et al. (1951) for the isolation of lactobacilli (see Keddie and Jones [1981] and Talon et al. [1988]). *Brochothrix thermosphacta* (no information is available for *B. campestris*) grows only poorly on the MRS medium of (De Man et al., 1960). Several different media based on peptone, yeast extract, and glucose or glycerol have been used for the isolation of *B. thermosphacta* (Sulzbacher and McLean, 1951; Wolin et al., 1957; Barlow and Kitchell, 1966; Gardner, 1966; Gardner, 1967). More recently, the streptomycin sulfate-thallous acetate-actidione (actidione = cycloheximide) agar medium (STAA) of Gardner (1966) has been used routinely for the selective isolation and enumeration of *B. thermosphacta* from meats, meat products, fish and a variety of other foods (Gardner, 1981). Although extremely useful for such materials, the selectivity of STAA is poor when soils or fecal samples are examined (Gardner, 1981). Talon et al. (1988) used STAA medium supplemented with nalidixic acid and oxacillin for the isolation of *B. thermosphacta* from soil, grass, feces, etc., and for the isolation of *B. campestris* from soil and grass.

Isolation of *Brochothrix thermosphacta* from Meats and Meat Products.

Swabs of various meat surfaces or samples of macerated meat or other materials are usually suspended in 0.1% (w/v) peptone water and shaken vigorously before plating on suitable media (see Gardner et al., 1967). Plates should be incubated at 22°C for up to 5 days, but colonies of *B. thermosphacta* are usually visible within 48 h.

The following media are suitable for the growth of *B. thermosphacta*.

Glycerol Nutrient Agar (Gardner, 1966; Gardner, 1967)

Peptone (Oxoid)	20 g
Yeast extract (Oxoid)	2 g
Glycerol	15 g
K_2HPO_4	1 g
$MgSO_4 \cdot 7H_2O$	1 g
Agar (Oxoid no. 3)	13 g

Dissolve ingredients and dilute up to 1 liter with distilled water. Adjust pH to 7.0 and autoclave at 121°C for 15 min.

Glucose Nutrient Agar (Sulzbacher and McLean, 1951; Wolin et al., 1957)

Tryptone (Difco)	10 g
Yeast extract (Difco)	5 g
K_2HPO_4	5 g
NaCl	5 g
Glucose	5 g
Agar	15 g

Dissolve ingredients and dilute up to 1 liter with distilled water. Adjust pH to 7.0 and autoclave at 121°C for 15 min.

Medium STAA for Selective Isolation of *Brochothrix thermosphacta* (Gardner, 1966)

Peptone (Oxoid)	20 g
Yeast extract (Oxoid)	2 g
Glycerol	15 g
K_2HPO_4	1 g
$MgSO_4 \cdot 7H_2O$	1 g
Agar (Oxoid no. 3)	13 g

Dissolve ingredients and dilute up to 1 liter with distilled water. Adjust pH to 7.0 and autoclave at 121°C for 15 min. To this sterile, molten medium, add the following solutions (prepared in sterile, distilled water) to give the final concentrations indicated; streptomycin sulfate (Glaxo), 500 µg/ml; cycloheximide (Upjohn), 50 µg/ml; and thallous acetate, 50 µg/ml).

After incubation of appropriate samples on this medium at 20–22°C for 48 h, a large majority of the colonies are *B. thermosphacta*; the exceptions are a few pseudomonads.

Modified Medium STAA for Selective Isolation of *Brochothrix* spp. from Grass, Soil, Feces, and Similar Material (Talon et al., 1988)

Prepare as for STAA medium but supplement with nalidixic acid (15 µg/ml) and oxacillin (5 µg/ml).

After incubation of appropriate samples on this medium at 20–22°C for 48 h, a large majority of the colonies are *Brochothrix* spp.

Enrichment of *Brochothrix* spp.

Enrichment of *Brochothrix* spp. is not usually performed, but holding meat or meat product samples under gas-permeable film at temperatures below 10°C can act as enrichment. Similar enrichment for other materials, grass or soil, could be useful but apparently has not been attempted.

Preservation of Cultures

Cultures may be preserved for short periods (6 months to 1 year) in nutrient agar (plus 0.1% glucose) stabs in screw-capped bottles stored in the dark at room or refrigeration temperature. Longer-term preservation (over 10 years with *Brochothrix thermosphacta*) may be achieved by freezing on glass beads at –60 to –70°C (Jones et al., 1984). Cultures may also be preserved by freeze drying (lyophilization).

CHAPTER 1.2.13

The Genus *Erysipelothrix*

ERKO STACKEBRANDT, ANNETTE C. REBOLI AND W. EDMUND FARRAR

The genus *Erysipelothrix* consists of three species, *Erysipelothrix rhusiopathiae* (Rosenbach, 1909), *Erysipelothrix tonsillarum* (Takahashi et al., 1987a) and the recently described *Erysipelothrix inopinata* (Verbarg et al., 2004). In 1876, Koch first isolated this slender, pleomorphic, Gram-positive bacillus from the blood of mice that had been inoculated subcutaneously with blood from putrefied meat (Koch, 1878) and was designated "*E. muriseptica*." In 1882, Loeffler observed a similar organism in the cutaneous blood vessels of a pig that had died of swine erysipelas and published the first good description of the organism (Loeffler, 1886). It is probable that a bacillus observed a few months previously by Pasteur and Dumas in pigs dying of rouget (swine erysipelas) was the same organism as that described by Loeffler (Pasteur and Dumas, 1882). Trevisan (1885) proposed the name "*E. insidiosa*." Rosenbach was the first to establish *Erysipelothrix* as a human pathogen. In 1909, he reported the isolation of the organism from a patient with localized cutaneous lesions and coined the term "erysipeloid" to distinguish these lesions from those of human erysipelas (Rosenbach, 1909). Subsequently, *Erysipelothrix* was identified as the cause of infection in many animal species.

Rosenbach distinguished three species, *E. muriseptica*, *E. porci* and *E. erysipeloides*, based on their murine, porcine, and human origins, respectively (Rosenbach, 1909). The name *Bacterium rhusiopathiae* (Migula, 1900) antedated the name *E. porci*. The combination *Erysipelothrix rhusiopathiae* was first proposed by Buchanan (1918). At least 36 names have appeared in the literature for species of this genus. With the appreciation that all strains belonged to a single species, the name *E. insidiosa* was proposed for *E. rhusiopathiae*, *E. muriseptica*, and *E. erysipeloides* (Langford and Hansen, 1953; Langford and Hansen, 1954). In 1966, Shuman and Wellmann proposed that the name *E. insidiosa* be rejected in favor of *E. rhusiopathiae* which means literally "erysipelas thread of red disease."

With more strains being subjected to taxonomic studies, the great variation in serological, biochemical, chemical and genomic properties of *E. rhusiopathiae* was noted (Erler, 1972; Feist, 1972; Flossmann and Erler, 1972; White and Miritikani, 1976; Takahashi et al., 1992) and consequently the species *E. tonsillarum* (also named "*E. tonsillae*" in the older literature [Takahashi et al., 1989] was described for avirulent *Erysipelothrix* strains of serotype 7, frequently isolated from the tonsils of apparently healthy pigs (Takahashi et al., 1987a). The species *E. inopinata* was isolated from sterile-filtered vegetable broth (Verbarg et al., 2004).

Erysipelothrix, the only genus of the family Erysipelotrichaceae (Verbarg et al., 2004), is defined as Gram-positive but may appear Gram-negative because it decolorizes readily. Strains are nonencapsulated, nonsporulating, nonmotile straight, or slightly curved, slender rods with rounded ends, but some show a tendency to form long filaments. Organisms are arranged singly, in short chains, or in pairs in a "V" configuration or are grouped randomly. They are not acid-fast. Menaquinones (MKs) are absent. The exact growth requirements of the organism have not been determined. Several amino acids, riboflavin, and small amounts of oleic acid are required (Hunter, 1942), and growth is enhanced by tryptophan (Ewald, 1981). Growth occurs at 15–44°C, with an optimal temperature of 30–37°C, and at a pH of 7.2–7.6 with a range of 6.7–9.2 (Sneath et al., 1951). The organism is a facultative anaerobe. Growth is improved by 5–10% carbon dioxide. Heating at 60°C for 15 min is lethal. *Erysipelothrix rhusiopathiae* is able to grow in the presence of 0.2% phenol, 0.1% sodium azide, 0.001% crystal violet, 0.05% potassium tellurite, 0.02% thallous acetate, and 0.2% 2,3,5, triphenyl-tetrazolium chloride (Sneath et al., 1951; Ewald, 1981). Cells are catalase-negative and oxidase negative. The cell wall is Gram positive; the murein belongs to the B-crosslinking type, having L-alanine in position three of the peptide subunit and an interpeptide bridge consisting of the peptide Gly→L-Lys→L-Lys. 16:0, *cis*-9-18:1 and 18:0 are the predominant fatty acids. Cells are aerobic to facultatively anaerobic, chemoorganotrophic with respiratory metabolism, and weakly fermentative. Acid but no gas produced from glucose and other carbo-

hydrates. The mol% of the DNA G+C is 36–40% (high pressure liquid chromatography [HPLC], melting temperature [Tm], and buoyant density [Bd]; Flossmann and Erler, 1972). Some strains pathogenic for mammals and birds.

Review-type coverage of the biology and clinical features of *Erysipelothrix* has been dealt with by Takahashi (Takahashi, 1996; in Japanese), Hill and Ghassemian (1997), Brooke and Riley (1999), Brouqui and Raoult (2001), and Boo et al. (2003), and in The Genus Erysipelothrix in the second edition.

Taxonomy and Phylogeny

Erysipelothrix was once thought to be closely related to *Listeria* (Barber, 1939), but results of studies of cell wall peptidoglycan (Schleifer and Kandler, 1972; Verbarg et al., 2004), fatty acid patterns (Tadayon and Carroll, 1971), DNA hybridization studies (Stuart and Welshimer, 1974), and numerical taxonomic studies (Davis and Newton, 1969; Stuart and Pease, 1972b; Jones, 1975; Wilkinson and Jones, 1977; Feresu and Jones, 1988) did not support this relationship. There are no common antigens between strains of *Erysipelothrix* and *Listeria monocytogenes* as detected by immunodiffusion or passive hemagglutination tests (Pleszczynska, 1972a; Pleszczynska, 1972b). Differences between the two genera have been demonstrated in cell wall chemistry by chromatography and infrared spectrophotometry. Paper and thin-layer chromatography (TLC) of acid hydrolysates of the purified cell wall show that *Erysipelothrix* is clearly distinguishable from *Listeria*. While members of *Erysipelothrix* have lysine and glycine in the cell wall (Mann, 1969), *Listeria* possesses *meso*-diaminopimelic acid.

In the 1980s, the genus *Erysipelothrix* was classified as a regular nonsporeforming Gram-positive rod (Jones, 1986). However, even earlier, enzyme and DNA-base ratio studies reveal a closer relationship of *Erysipelothrix* to the family Lactobacillaceae than to Corynebacteriaceae (Flossmann and Erler, 1972; White and Mirikitani, 1976). In a study of more than 200 strains of coryneform bacteria using 173 morphological, physiological, and biochemical tests and computer analysis, eight clusters were identified, and *Erysipelothrix* was most closely related to *Streptococcus pyogenes* (Jones, 1975). In another study, the closest similarity of *Erysipelothrix* was to the genus *Gemella* (Wilkinson and Jones, 1977). In general, results of numerical taxonomic studies indicate that strains of *E. rhusiopathiae* form a distinct cluster that shows the closest similarity to the streptococci (Jones, 1986).

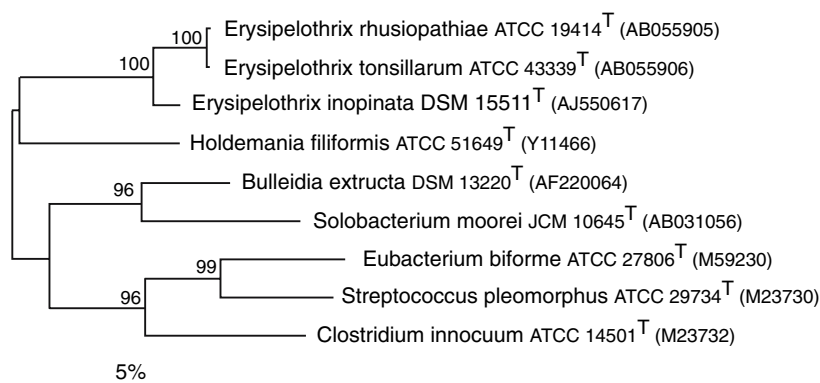
With the introduction of 16S rRNA gene sequence analyses, the phylogenetic position has been elucidated and today the genus is considered a member of the Firmicutes (Kiuchi et al., 2000; Verbarg et al., 2004) belonging to the family Erysipelothricaceae (*Clostridium* cluster XVI according to Collins et al., 1994, and Verbarg et al., 2004), a lineage that also embraces *Holdemania filiformis* (Willems et al., 1997). Less closely related are *Bulleidia extructa* (Downes et al., 2000), *Solobacterium moorei* (Kageyama et al., 2000), and nonauthentic members of *Eubacterium*, *Streptococcus* and *Clostridium* (see Fig. 1). The 16S rRNA gene sequences of the *E. rhusiopathiae* strain [{genbank}{AB055905}] is highly similar to the sequence of *E. tonsillarum* [{genbank}{AB055906}] (99.8% similarity). DNA-DNA reassociation values obtained for these strains range only between 18 and 36%, which confirm differences at the physiological level, hence their separate species status. The 16S


Fig. 1. 16S rRNA gene sequence dendrogram (De Soete, 1983) displaying the phylogenetic position *Erysipelothrix* strains among some phylogenetic neighbors. Similarity values obtained for almost complete sequences were transformed into phylogenetic distance values that compensate for multiple substitutions at any given site in the sequence (Jukes and Cantor, 1969). Numbers indicate the percentage of bootstrap (> 95%) samplings (Felsenstein, 1993), derived from 1000 resamplings. Bar indicates sequence divergence. Numbers in parentheses are accession numbers of 16S rRNA gene sequences.

rRNA gene sequence of *E. inopinata* [{gen-bank}{AJ550617}] is less than 97.5% similar to that of the other two type strains, while it shares 99.9% similarity to that of strain Pecs 56 ([{gen-bank}{AB055907}]) listed as unpublished in the European Molecular Biology Laboratory (EMBL) database. 16S rDNA gene sequences of *E. rhusiopathiae* strains serotype 13 ([{gen-bank}{AB019249}]) and serotype 18 ([{gen-bank}{AB019250}]; Takeshi et al. 1999), covering the 3' half of the molecule (about 790 nucle-otides), share 97.5 and 97.8% similarity, re-spectively, with the corresponding fragment of the gene of strain DSM 15511^T [{gen-bank}{AB019250}].

Habitats

Occurrence in Animals

Erysipelothrix rhusiopathiae and infections due to this organism occur worldwide. It has been found as a commensal or a pathogen in a wide variety of vertebrate and invertebrate species, including "swine, sheep, cattle, horses, dogs, wild bears, kangaroos, reindeer, mice, wild rodents, seals, sea lions, cetaceans, mink, chipmunks, crus-taceans, fresh and salt-water fish, crocodiles, caimans, stable flies, house flies, ticks, mites, mouse lice, turkeys, chickens, ducks, geese, guinea fowl, pigeons, sparrows, starlings, eagles, parrots, pheasants, peacocks, quail, parakeets, mud hens, canaries, finches, siskins, thrushes, blackbirds, turtledoves, and white storks" (Conklin and Steele, 1979; see also Creech, 1921; Gledhill, 1948; Woodbine, 1950; Sneath et al., 1951, Hunter, 1974, and Wood, 1975). Recent reports verify the occurrence in chickens (Mohan et al., 2002), chicken meat (Nakazawa et al., 1998), dogs (Takahashi et al., 1993; Taka-hashi et al., 2000), wild boars (Yamamoto et al., 1999), moose (Campbell et al., 1994), opossum (Lonigro and LaRegina, 1988), and retail pork and fish (Stenstrom et al., 1992). Some of the reports on *E. rhusiopathiae* may actually cover strains of *E. tonsillarum*. The major reservoir of *E. rhusiopathiae* is generally believed to be domestic swine, but rodents and birds are also frequently infected. The organism causes no known disease in fish but can grow and persist for long periods in the mucoid exterior slime of these animals (Wood, 1975).

The presence of *E. rhusiopathiae* in the external environment is probably secondary to contamination by infected animals; it may be found in sewage effluent from abattoirs and on ground contaminated with the feces of animals with apparent or inapparent infection. It now appears that, contrary to previous belief, the organism is not able to exist indefinitely in soil, but it may live long enough to cause infection in animals or humans weeks or months after initial soil contamination. Pathogenic strains of *E. rhusiopathiae* have been isolated from the feces of apparently healthy swine, and asymp-tomatic swine commonly harbor this organism in their tonsils and other lymphoid tissues (Wood, 1974a). Some of these isolates are included in *E. tonsillarum* (Takahashi et al., 1987a). Isolates of the genus have also been recovered from the tonsils of healthy cattle in Japan (Hassanein et al., 2001). A cycle may thus occur in which asymptomatic carrier swine contaminate the soil of the swine pens, and organisms in the soil are transmitted to previ-ously uninfected animals, some of which become asymptomatic carriers of these bacte-rial strains.

Occurrence in Humans

The risk of human infection with *E. rhusio-pathiae* is closely related to the opportunity for exposure to the organism (McGinnes and Spindle, 1934). Relation to age, sex, race, and socioeconomic status appears to reflect only opportunity for exposure. Most human cases are related to occupational exposure. Individu-als at greatest risk for infection include butch-ers, fishermen, fish handlers, abattoir workers, veterinarians and housewives (Klauder, 1938; Morrill, 1939; Woodbine, 1950; Hillenbrand, 1953; Hunter, 1974; Wood, 1975; Conklin and Steele, 1979; Gorby and Peacock, 1988), but erysipelothrix infection has been associated with a wide variety of occupations including "butchers, meat cutters, meat-processing work-ers, poultry-processing workers, meat inspec-tors, rendering plant workers, knackers, animal caretakers, farmers, fishermen, including lobster fishermen, fish and lobster handlers, fish-processing workers, crab and crayfish-processing workers, clam openers, veterinarians, including veterinary students, cooks, bakers, housewives, kitchen workers, food handlers, caterers, button makers (bone), game handlers, furriers, leather workers, soap makers, fertilizer workers, sewer workers, bacteriologists, laboratory workers, and stockyard workers" (Wood, 1975). Infec-tion is especially common among individuals who handle fish. Hunter (1974) noted the occurrence of "fish-handlers'" disease among "fishermen, fish cleaners, gutters and picklers, fish porters, fish-box repairers, fish-lorry drivers, fish-meal workers, smoke driers, fishmongers, cooks and housewives who infect themselves through abrasions of the skin caused by the spines, fins, and bones of fish, especially skate." During World War II, outbreaks of the disease

occurred in factories in Norway where fish was dried and tinned and cod heads made into fertilizer; the delay caused by the need of fishing boats to sail in convoy apparently allowed the organisms to multiply, resulting in the high incidence of infections (Hunter, 1974). Diseases called "seal finger" and "whale finger" occur in those who capture these animals and scratch their hands on the steel ropes used in their work (Hillenbrand, 1953). Anglers may be infected through puncture wounds made by fish hooks or the teeth of fish, or by the claws of lobsters and crabs; in the series of 329 cases of erysipeloid described by Gilchrist, 323 were caused by injuries produced by crabs (Gilchrist, 1904). Abattoir workers, meat porters, butchers and poulterers may become infected through small cuts from the knives they use or through abrasions caused by splinters of bone (a condition called "pork finger"). Veterinary pathologists may become accidentally inoculated by injury from knives or bone splinters during necropsy of infected animals, particularly poultry. Workers who peel potatoes and other root vegetables may become infected by earth contaminated with the manure of infected animals.

Most cases in humans and other animals probably occur via scratches or puncture wounds of the skin, but in some cases it appears that the organism has penetrated intact skin (McGinnes and Spindle, 1934). Human-to-human infection has not been documented. Although *E. rhusiopathiae* is killed by moist heat at 55°C for 15 minutes, it is resistant to many environmental influences, including salting, pickling, and smoking (Conklin and Steele, 1979). Meat and bacon may contain the organism after pickling for 170 days or after 30 days in a mixture of salt and potassium nitrate, and the organism has been recovered from ham after smoking. It may remain alive for 12 days in direct sunlight, and for many months in carcasses left to decay on the surface of the ground or buried as deep as 7 feet. It has also been found in city sewage containing drainage from abattoirs and stables.

Reporting of infections due to *E. rhusiopathiae* is not required by health authorities, so it is difficult to know whether the incidence of these infections is increasing or decreasing. Some technological changes in industries employing animal products have probably resulted in reduced contact between *E. rhusiopathiae* and humans. For example, nearly all buttons are now made of plastic, rather than bone. To the extent that such changes reduce occupational exposure to the organism, the future incidence of erysipeloid, and more serious forms of infection with *E. rhusiopathiae*, will decline.

Diseases Due to Erysipelothrix rhusiopathiae

Disease in Animals

Swine erysipelas is worldwide in distribution. It was first recognized as an important disease in the United States during the 1930s, and by 1959 it had been reported from 44 states. The incidence then declined to a relatively low level by 1972, where it has remained. The present low prevalence of swine erysipelas, in spite of the widespread distribution of the organism, may be attributible largely to management practices such as maintenance of closed herds, use of confinement housing, improved waste disposal, vaccination, and use of antibiotics in feed (Wood, 1984).

Four clinical entities have been described in swine: 1) an acute septic form, in which the animals may die within a few days; 2) a subacute urticarial form marked by reddish purple rhomboid spots or "diamonds" in the skin (diamond skin disease); 3) a joint or arthritic form; and 4) a chronic cardiac form (endocarditis; Klauder, 1944; Gledhill, 1948; Woodbine, 1950; Wood and Shuman, 1974b).

In sheep, the typical form of the disease is polyarthritis, which begins when the lambs are 2–3 months old (Conklin and Steele, 1979). The gait becomes stiff, and the animals have difficulty rising and may fall down. The involved joints are usually swollen and the capsule is thickened. The organism can be cultured from the joint tissue. There are no lesions in visceral organs.

Erysipelothrix rhusiopathiae causes disease in many species of birds (Conklin and Steele, 1979). Adult male turkeys develop a disease called "bluecomb" because of the cyanotic skin color. The birds become droopy, develop diarrhea, and die. Hemorrhagic lesions are found in the breast and leg muscles, pericardium, liver and spleen, and the organism is easily isolated from these tissues. Large outbreaks have also occurred in domestic ducks, less commonly in chickens.

Although the greatest commercial impact of *E. rhusiopathiae* infection is due to disease in swine, infection of sheep, turkeys, and ducks is also of economic importance (Conklin and Steele, 1979). Both killed bacterin vaccines (formalin-killed whole culture adsorbed on aluminum hydroxide gel) and live avirulent vaccines have been available in the United States since the 1950s. Both are prepared from organisms of serovar 2 but provide cross-protection against many (but not all) other serovars (Sawada and Takahashi, 1987). Effectiveness of killed and live vaccines appears to be approximately equal (Schuman, 1959). Usage in the United States has

roughly paralleled the incidence of swine erysipelas. Killed bacterins have also been used in turkeys, primarily during epizootics. An effective live avirulent vaccine that can be administered in drinking water has also been developed recently (Bricker and Saif, 1988).

Disease in Humans

The spectrum of disease seen in humans closely parallels that seen in swine (Klauder, 1926; Sikes, 1958; Grieco and Sheldon, 1970; Phillips, 1986). There are three well-defined clinical categories of human disease: 1) a localized cutaneous form, erysipeloid; 2) a generalized cutaneous form; and 3) a septicemic form, which is often associated with endocarditis (Grieco and Sheldon, 1970).

LOCALIZED CUTANEOUS FORM OR ERYSIPELOID OF ROSENBACH Erysipeloid is a localized skin infection that is actually a cellulitis. Because of its mode of acquisition, contact with infected animals, fish, or their products, with organisms gaining entrance via cuts or abrasions on the skin, lesions are usually confined to the fingers and hands. The patient complains of pain and swelling of the finger or part of the hand. The pain is often severe and may be described as a burning, throbbing or itching. A history may be elicited of an infected scratch or wound due to a bone or knife contaminated by animal secretions approximately 5–7 days or, at most, 2 weeks prior to the onset of symptoms (Price and Bennett, 1951). The infected area is swollen. The lesion consists of a well-defined, slightly elevated, violaceous zone that spreads peripherally as discoloration of the central area fades (King, 1946). Systemic effects are uncommon. Low-grade fever and arthralgias occur in approximately 10% of cases and lymphangitis and lymphadenopathy in approximately one third (Nelson, 1955). There may be arthritis of an adjacent joint. Vesicles may be present, but suppuration does not occur. The absence of suppuration along with the violaceous color, lack of pitting edema, and disproportionate pain help to distinguish erysipeloid from staphylococcal or streptococcal infection. Erysipeloid is a self-limited condition, the lesions usually resolving without therapy within 3 or 4 weeks.

DIFFUSE CUTANEOUS FORM This is a rare situation in which the violaceous cutaneous lesion progresses proximally from the site of inoculation or appears at remote areas (Ehrlich, 1946; Grieco and Sheldon, 1970). Bulla formation may occur. The patients often have systemic manifestations such as fever and joint pains, but blood cultures are negative. The clinical course is much more protracted than in the localized disease form, and recurrences are not uncommon. In one instance, a butcher who ate sausage from a pig slaughtered because of swine erysipelas developed widespread urticaria with the rhomboid pattern characteristic of swine erysipelas (Hunter, 1974).

SEPTICEMIA AND ENDOCARDITIS Systemic *E. rhusiopathiae* infection is uncommon. No cases of systemic disease were seen among the 500 cases of erysipeloid described by Nelson (1955) or among the 329 cases reported by Gilchrist (1904). Fifty cases of *E. rhusiopathiae* infection associated with an extremely high incidence of endocarditis (90%) were reported between 1940 and 1988 (Reboli and Farrar, 1989). All reported cases of endocarditis except one involving a Starr-Edwards prosthetic aortic valve (Gransden and Eykyn, 1988) were of native valves. Only about one-third of patients had a history of an antecedent skin lesion or a concurrent characteristic skin lesion of erysipeloid (Gorby and Peacock, 1988). Gorby and Peacock (1988) compared clinical features of *E. rhusiopathiae* endocarditis with those of endocarditis caused by other bacteria (Kaye, 1976). They found a higher male-to-female ratio (which probably reflects occupational exposure), a greater propensity for involvement of the aortic valve, and a much higher mortality rate (38%) among patients with *E. rhusiopathiae* endocarditis. There was more prior heart disease among those with endocarditis caused by other organisms. In nearly 60% of patients, *E. rhusiopathiae* endocarditis apparently developed on previously normal heart valves. The clinical picture with respect to fever, peripheral skin stigmata of endocarditis, emboli, splenomegaly, hematuria, and mycotic aneurysm was similar for the two groups. Very few cases of endocarditis have occurred in immunocompromised patients, but a history of alcohol abuse was present in 33%. The presentation is most often subacute but may be acute (Schiffman and Black, 1956; Simberkoff and Rahal, 1973; Gorby and Peacock, 1988). The most common complication of endocarditis, congestive heart failure, was present in approximately 80% of patients (Russell and Lamb, 1940; Grieco and Sheldon, 1970; McCracken et al., 1973; Heggers et al., 1974; Kramer et al., 1982; Fliegelman et al., 1985). Myocardial abscesses and aortic valve perforation have been reported (Russell and Lamb, 1940; Heilman and Herrell, 1944; Morris et al., 1965; Fowler et al., 1967; Mandal and Malloch, 1971; Kramer et al., 1982). More than one-third of patients required valve replacement (Gorby and Peacock, 1988). Diffuse glomerular nephritis and meningitis have also been reported

as complications (Silberstein, 1965; Simberkoff and Rahal, 1973). Ognibene et al. (1985) reported the first case of septic shock associated with this organism in a patient without convincing evidence of endocarditis. A recent Medline survey on *Erysipelothrix* found very few clinical case reports (Schuster et al., 1993; Hill and Ghassemian, 1997).

OTHER   INFECTIONS Osseous necrosis of the thumb has been reported in a patient who developed fatal endocarditis (Klauder et al., 1943), and Torkildsen (1943) described a case of intracranial abscess. Chronic arthritis has been reported in a few cases in Europe (Ehrlich, 1946).

Treatment

The mainstay of treatment of infections caused by *E. rhusiopathiae* is antibiotic therapy. Although skin lesions usually heal spontaneously within 4 weeks, second attacks may occur and lesions may persist for months. Healing is hastened by antibiotic therapy. Susceptibility data are limited. Most strains are highly susceptible to penicillins, cephalosporins, erythromycin and clindamycin (Heilman and Herrell, 1944; Stiles, 1947; Sneath et al., 1951; Poretz, 1985; Gorby and Peacock, 1988). Minimal inhibitory concentrations for penicillins have been reported to range from 0.0025 to 0.06 µg/ml, with minimal bactericidal concentrations of 0.0025–0.75 µg/ml (Gorby and Peacock, 1988). Susceptibility to chloramphenicol and tetracycline is variable. Most strains are resistant to sulfonamides, trimethoprim-sulfamethoxazole, aminoglycosides, vancomycin, novobiocin and polymyxins. Resistance to vancomycin is noteworthy because this agent is often used in empiric therapy of prosthetic valve endocarditis and in the treatment of native valve endocarditis due to Gram-positive organisms in individuals who are allergic to penicillins.

Penicillin G, in doses of 12–20 million units/day, is the drug of choice for serious infections caused by *E. rhusiopathiae* (Poretz, 1985). Recommended duration of therapy for endocarditis is 4–6 weeks, although shorter courses consisting of 2 weeks of intravenous therapy, followed by 2–4 weeks of oral therapy have been successful (Muirhead and Reid, 1980; Ognibene et al., 1985). There has been no reported experience in the treatment of penicillin-allergic patients. Cephalosporins are the most appropriate alternatives since both clindamycin and erythromycin are only bacteriostatic agents. Valve replacement has been necessary in about one-third of cases of endocarditis.

Pathogenesis and Pathology

The factors responsible for virulence in *E. rhusiopathiae* are not clearly defined. Most strains isolated from pigs with swine erysipelas belong to serotypes 1a, 1b and 2. Serotype 1a is most common in septicemia. Ability to adhere to mammalian cells may be an important determinant of virulence. Virulent strains of *E. rhusiopathiae* adhere much more avidly than avirulent strains to porcine kidney cell lines (Takahashi et al., 1987b), and strains isolated from swine with endocarditis or septicemia adhere more strongly to swine heart valve tissue in vitro than other isolates of *E. rhusiopathiae* (Bratberg, 1981). *Erysipelothrix rhusiopathiae* also produces a hyaluronidase and a neuraminidase, which cleaves α-glycosidic linkages of sialic acid, a mucopolysaccharide on the surface of mammalian cells. Neuraminidase activity is higher in virulent than in avirulent strains (Krasemann and Müller, 1975), and there is evidence that this enzyme may play a role in the pathogenesis of arthritis and thrombocytopenia in rats experimentally infected with *E. rhusiopathiae* (Shinomiya and Nakato, 1985; Nakato et al., 1986).

Intravenous injection of the organism into rabbits is fatal in 2–3 days. An erysipeloid rash develops in the injected ear, the lungs become hemorrhagic, and a pericardial exudate develops. Congestion of the viscera is noted with pinpoint focal necrosis in the liver and mononuclear cell infiltrates in the spleen (Smith, 1983). On histopathological examination, bacilli are scarce. Inoculation of the conjunctiva produces conjunctivitis, which is often followed by fatal disseminated infection. Subcutaneous injections seldom cause death.

The rhomboidal skin lesions described in swine are the result of thrombotic vasculitis of end arterioles (Grieco and Sheldon, 1970). Injection of the organism into swine produces an inflammatory polyarthritis, lymphadenopathy, endocarditis, peripheral monocytosis, and focal necrosis of the liver and myocardium (Smith, 1983). The endocarditis in swine usually involves the mitral valve and there is a tendency for the vegetations to invade the mural endocardium (Russell and Lamb, 1940). Pathological changes in human cases of septicemia and endocarditis are indistinguishable from changes caused by other bacterial organisms.

Fatal septicemia occurred in a wild-caught opossum two months after capture of the animal. *Erysipelothrix rhusiopathiae* was isolated from heart blood, liver, spleen and lungs (Lonigro and LaRegina, 1988). Although no evidence of endocarditis was found, when this strain was inoculated intravenously into previously healthy opossums, all of three animals developed vege-

tations on the atrioventricular valve. Brown and Brenn stains revealed small Gram-positive rods within the vegetations, but the organism could not be grown from blood or vegetations of any of the animals (LaRegina et al., 1988).

Swine arthritis bears some similarities to human rheumatoid arthritis (Sikes, 1958; Grieco and Sheldon, 1970; Phillips, 1986). It is marked by pannus formation with destruction of cartilage at the site of pannus attachment, intra-articular fibrous adhesions, and subchondral cellular reaction (Sikes, 1958; Grieco and Sheldon, 1970). Antigens of *E. rhusiopathiae* have been detected by electron microscopy and immunofluorescence in deep joint tissues of swine as long as 18 months after infection. It is not known whether development of chronic arthritis is due to specific immune reactions against *E. rhusiopathiae* or to autoimmune reactions or both (Wood, 1984).

Bacteriology

Morphology, Growth, and Biological and Chemical Properties

The cell wall of *E. rhusipathiae* contains a peptidoglycan based on lysine (Feist, 1972). More detailed analysis of the peptidoglycan structure using the method described by Schleifer and Kandler (1972) and Schubert and Fiedler (2001) indicate that the hallmark of *Erysipelothrix* is the presence of a B-cell wall type in which the peptide bridge is formed between amino acids at positions 2 and 4 of adjacent peptide side chains and not, as in the vast majority of bacteria, between amino acids at positions 3 and 4. The B-type occurs not only in *Erysipelothrix* but also in some other members of the Clostridium subphylum, e.g., *Holdemania*, *Acetobacterium*, *Clostridium barkeri* and *Eubacterium limosum*, and

within the family Microbacteriaceae, order Actinomycetales (Schleifer and Kandler, 1972). The two-dimensional thin-layer chromatogram of the partial acid hydrolysate of strain MF-EP02[T] revealed (besides the presence of lysine, glutamic acid, glycine, serine, alanine, muramic acid and glucosamine) the fragments D-Glu→Gly, L-Ser→D-Glu and L-Lys→L-Lys, but no aspartic acid or fragments containing aspartic acid. The quantitative amino acid composition (Mackenzie, 1987) is Ala:Gly:Ser:Glu:Lys = 1.7:0.7:0.9:1.0:1.5. It can thus be deduced that the peptidoglycan type is B1δ with the interpeptide bridge being Gly→L-Lys→L-Lys. The peptidoglycan composition (identical in the type strains of all three *Erysipelothrix* species) differs from that of *Holdemania filiformis* [{ATCC 51649}][T] [{genbank}{Y11466}] (the nearest, although remote, neighbor), which has L-Asp→L-Lys interpeptide bridges (Willems et al., 1997).

Several sugars occur in the cell wall (arabinose, galactose, glucose, glucose-6-phosphate, galactose-6-phosphate, ribose and xylose). Monosaccharide patterns show that there are three chemovars, which do not correlate with the serovars (Feist, 1972).

Mycolic acids are not present. Cellular fatty acid composition (mainly used to identify asporogenous, aerobic Gram-positive rods) of *E. tonsillarum* and/or *E. rhusiopathiae* has been reported by Julak et al. (1989), Bernard et al. (1991), von Graevenitz et al. (1991), and Takahashi et al. (1994). The most comprehensive fatty acid methyl ester (FAME) analysis of *Erysipelothrix* (Verbarg et al., 2004) was in extracts of methanolysates and was performed using the MIDI microbial identification system as described by Sasser (1990). The composition of fatty acids (Table 1) reveals high similarity of all strains of the *Erysipelothrix* species. A dendro-

Euclidian distance
gram of FAME relationships is depicted in Fig. 2. The pattern is dominated by C18:1-*cis*-9 (>30%), C16:0 (>24%) and C18:0 (>10%) FAMEs. This pattern differs from that of *Holdemania filiformis* which contains higher amounts of C18:1-*cis*-9 (50%), additional minor components and significant amounts of dimethyl acetal (C18:1-*cis*-9 [12%] and C16:0 [4%]) (Willems et al., 1997). Figure 2 is a dendrogram of relationship based on Euclidian distance estimated from a comparison of fatty acid methyl ester patterns.

L-Forms of *E. rhusiopathiae* have been described (Stuart, 1972a; Pachas and Currid, 1974; Todorov, 1976).

None of the *Erysipelothrix* strains contained significant amounts of menaquinones, no matter which growth conditions were used for the preparation of isoprenoid quinones (aerobic and anaerobic growth conditions on trypticase soy broth [TSB] agar + 5% sheep blood). Only traces of menaquinone (MK)-7 were detected in cells of *E. tonsillarum* DSM 14972[T] following aerobic cultivation (Collins and Jones, 1981; Verbarg et al., 2004). Isoprenoid quinones extraction by chloroform/methanol (2 : 1, v/v) from lyophilized cells, purification by preparative TLC on silica gel, and analyses by HPLC followed described methods (Collins et al., 1977; Groth et al., 1996).

Metabolic properties of type strains of *Erysipelothrix* species, determined by using the API 32 STREPT and BIOLOG GP microplate panel are indicated in Table 2.

CHARACTERIZATION OF *ERYSIPELOTHRIX RHUSIOPATHIAE* On blood agar this organism may be α-hemolytic but never β-hemolytic (see Table 3). There is a dual colonial and microscopic appearance (Figs. 3 and 4). After growing 24–48 h at 37°C on trypticase soy agar containing 5% sheep blood, colonies (known as smooth or S-forms) are very small (0.1 mm in diameter), convex, circular and transparent with a smooth glistening surface and edge. In older cultures, colonies are slightly larger and have opaque centers. Larger (0.2–0.4 mm diameter) flatter colonies with a matte surface and fimbriated edge are R-form or rough colonies. They may resemble miniature *Bacillus anthracis* colonies (Wilson and Miles, 1975). Both forms are usually light blue or sometimes green when viewed with oblique illumination. Intermediate forms are also seen (Barber, 1939; Ewald, 1981). S-form colonies dissociate to give rise to intermediate and R-form colonies. R-form colonies also give rise to S-forms (Ewald, 1962; Wawrzkiewicz, 1964). During these changes in morphology and cultural characteristics, there are also changes in virulence and antigenic properties. (The type-specific antigens remain unchanged.) In broth, S-form organisms cause a slight turbidity and a powdery deposit; R-forms have a tangled hair-like appearance. Microscopically, S-form organisms are the small, straight or slightly curved rods characteristic of the genus and measure 0.3–0.6 μm by 0.8–2.5 μm, while R-form organisms form long nonbranching filaments which may have a beaded appearance and which can be greater than 16 μm in length. Both forms stain evenly and may show deeply stained granules. Morphology varies with the medium, pH, and temperature of incubation. Acidic pH and temperature of 37°C favor R-forms (Wilson and Miles, 1975). Alkaline pH (7.6–8.2) and temperature of 30°C favor S-forms (Grieco and Sheldon, 1970). S-form organisms are seen in smears from blood and tissue and in acute forms of illness such as sepsis; R-forms (or S-forms and R-forms) are seen in more chronic conditions such as endocarditis or arthritis (Ewald, 1981).

Growth of *E. rhusiopathiae* is improved by blood or 5–10% serum, tryptophan and glucose. The best growth occurs in 0.1% glucose broth or on 0.5% glucose agar. Larger amounts of glucose may be inhibitory. Glucose metabolism is via the Embden-Meyerhof-Parnas pathway, with a small amount by the hexose monophosphate shunt (Robertson and McCullough, 1968). Exogenous

[a]As determined by API 32 STREPT and BIOLOG GP microplate panel.

[b]According to API 32 STREPT, all strains were positive for glycyl-tryptophan arylamidase, pyroglutamic acid arylamidase, and for acid production from glucose. All strains were negative for oxidase, aminopeptidase, hydrolysis of starch, gelatin liquefaction, DNA and casein, urease, acid from mannitol, sorbitol, raffinose, sucrose, L-arabinose, D-arabitol, cyclodextrin, glycogen, pullulan, maltose, melibiose, melezitose, tagatose, β-glucoronidase, production of acetoin and hydrolysis of hippurate.

[c]As determined with Biolog GP, all strains use the following substrates: adenosine, uridine, methylpyruvate, *N*-acetylglucosamine and α-D-glucose. All strains are negative in β-methyl-D-glucoside, D-tagatose, lactamide, alaninamide, D-arabitol, lactulose, α-methyl-D-mannoside, D-lactic acid methyl ester, D-alanine, β cyclo-dextrin, maltose, palatinose, turanose, L-lactic acid, L-alanine, dextrin, maltotriose, xylitol, D-malic acid, L-asparagine, glycogen, D-mannitol, D-raffinose, L-malic acid, inulin, L-fucose, L-rhamnose, acetic acid, L-glutamic acid, adenosine-5′-monophosphate, mannan, D-melezitose, α-hydroxy-butyric acid, mono-methyl succinate, glycyl-L-glutamic acid, thymidine-5′-monophosphate, Tween 40, D-galacturonic acid, D-melibiose, β-hydroxy-butyric acid, propionic acid, L-pyroglutamic acid, uridine-5′-monophosphate, Tween 60, α-methyl D-galactoside, sedoheptulosan, γ-hydroxy-butyric acid, pyruvic acid, L-serine, fructose-6-phosphate, D-gluconic acid, β-methyl D-galactoside, D-sorbitol, *p*-hydroxy-phenyl acetic acid, succinamic acid, putrescine, glucose-1-phosphate, stachyose, α-keto glutaric acid, succinic acid, 2,3-butanediol, glucose-6-phosphate, amygdalin, *m*-inositol, α-methyl D-glucoside, sucrose, α-keto valeric acid, *N*-acetyl L-glutamic acid and D-L-α-glycerol phosphate.

citrate is not used. Fermentative activity is weak (Smith, 1983). The fermentation pattern varies with the basal medium used (White and Shuman, 1961; Wood, 1970). Acid production from carbohydrates is usually poor or inconsistent when in 1% peptone water. It is recommended that 5–10% horse serum be added to the basal medium (White and Shuman, 1961; Wood, 1970; Seeliger, 1974), but since this is not always convenient, one may test for acid production in nutrient broth with 0.5–1% of the test carbohydrate and phenol red added as an indicator. In addition to lactic acid, small amounts of acetic acid, formic acid, ethyl alcohol, and CO_2 are produced from

the fermentation of glucose. Acid without gas is produced within 48 h from glucose, lactose, fructose and galactose (Karlson and Merchant, 1941). A few strains produce acid from maltose fermentation in 6–7 days. Xylose, mannitol, and sucrose are not fermented. This genus is indole and Voges-Proskauer negative and usually methyl red negative (Sneath et al., 1951). The methyl red test may be weakly positive when performed in a broth containing peptone, yeast extract, glucose, potassium phosphate, magnesium sulfate, and manganese sulfate (Wilkinson and Jones, 1977). There is no discoloration of methylene blue milk, little or no change in litmus

milk, and no reduction of nitrate. Urea, esculin, sodium hippurate, starch, cellulose and casein are not hydrolyzed. Xanthine and tyrosine are not degraded. The majority of strains produce hydrogen sulfide, but results can vary with the medium used (Ewald, 1964). Hydrogen sulfide production is an important test. It is best carried out on triple sugar iron agar (TSI) slants, in which hydrogen sulfide causes a blackened butt (Wood, 1970). An occasional old laboratory strain does not produce detectable hydrogen sulfide in TSI agar. Gelatin stab cultures yield a very characteristic pattern of growth described as a "test tube brush" or a "pipe cleaner" (Ewald, 1964; Weaver, 1985; Jones, 1986). After 24 h, growth is faint, hazy and limited to an area just below the surface. Within a few days, however, growth extends in a column to the bottom of the tube. There is no liquefaction of the gelatin. S-forms produce fine horizontal outgrowths that extend only 2–3 mm from the stab in a typical "pipe-cleaner" pattern (Ewald, 1964). R-forms extend further out and look like a "test-tube brush" (Fig. 5). This test is not convenient for most laboratories to do since the gelatin must be incubated at 22–25°C to maintain its solid state. Furthermore, this test is not required for identification.
Fig. 5. Three *Erysipelothrix* strains on ferrochloride-gelatin medium after incubation of 48 h at 20°C. On the left, smooth strain; in the middle and on the right, dissociated strains.

Most known strains produce hyaluronidase (Ewald, 1957). There may be a correlation between production of this enzyme and virulence. Good producers of hyaluronidase usually belong to serovar 1 (Ewald, 1957; Ewald, 1981). All strains produce neuraminidase but in varying amounts. There is a good correlation with virulence (Krasemann and Müller, 1975; Müller and Seidler, 1975; Müller and Krasemann, 1976; Nikolov and Abrashev, 1976). There are also virulent strains that do not produce neuraminidase or which produce small amounts. Synthesis of this enzyme depends on the growth phase of the bacteria. There is maximum production at the end of the logarithmic phase of growth (Abrashev and Zamfirova, 1976).

Characterization of *Erysipelothrix Tonsillarum* (Takahashi et al., 1987a) In addition to the genus specific properties and characters listed in Table 2, the rods are approximately 0.3 μm wide by 1.0–1.5 μm long. Surface colonies on brain heart infusion (BHI) agar after 2 days of incubation are punctiform to approximately 1 mm in diameter, circular, entire, convex, colorless, transparent and soft. Though *E. tonsillarum* is described to be morphologically and biochemically indistinguishable from the 10 strains of *E. rhusiopathiae* included in the study by Takahashi et al. (1987a), the two species differ in their acid production from maltose (*E. rhusiopathiae* is negative, *E. tonsillarum* positive). In addition to reactions indicated in Table 2, acid production is obtained from dextrin and levulose; weak acid production from mannose; and no acid from glycerol, salicin, inositol, dulcitol, raffinose, mannitol, rhamnose, trehalose, xylose, sorbitol and arabinose. Litmus milk is not acidified. *Erysipelothrix tonsillarum* isolates are susceptible to penicillin G, ampicillin, and erythromycin but not to kanamycin and sulfadi-methoxine.

Characterization of *Erysipelothrix Inopinata* (Verbarg et al., 2004) In addition to the genus specific properties and characters listed in Table 2, the rods are approximately 0.5 μm wide and 1.5–3.0 μm long. Surface colonies on BHI (Difco) after 2 days of incubation are punctiform to approximately 1.5 mm in diameter, creamy white, undulate, convex, translucent and soft. Growth occurs under aerobic and anaerobic conditions in BHI and Columbia blood media, preferably at pH 8. Growth occurs at 20°C and 40°C, but not at 45°C. The optimal temperature for growth is 25–30°C. The mol% G+C of DNA is 37.5 (HPLC). Type strain is *Erysipelothrix inopinata* DSM 15511^T (CIP 107935^T).

Specimen Collection, Transport, and Maintenance

Routine blood culture techniques are adequate for specimen collection and organism growth in suspected cases of sepsis or endocarditis (Muirhead and Reid, 1980). Because organisms are located only in deeper parts of the skin in cases of erysipeloid, aspirates or biopsy specimens from the edge of the lesion are needed to obtain the organism (Price and Bennett, 1951). Biopsy should be of the entire thickness of the dermis. The organism may also be obtained from cases of erysipeloid by injecting saline into the edge of the lesion and aspirating some of the injected saline for culture (Smith, 1983).

Immediately after collection, the specimen should be put into an infusion broth of 1% glucose and kept at room temperature or refrigerated until it reaches the laboratory. Cultures can be maintained for several months by stab inoculation into tubes of nutrient agar (pH 7.4; Jones, 1986). Freeze drying or freezing on glass beads at −70°C (Feltham et al., 1978) as well as storage under liquid nitrogen, is appropriate for long-term maintenance.

In many countries, *E. rhusiopathiae* is classified as a risk group 2 pathogen and specific rules and regulations apply for its shipment at the national and international level (see Rohde, 1999).

Isolation and Identification

Commercially available blood culture media are satisfactory for primary isolation from blood since *E. rhusiopathiae* is not particularly fastidious. Biopsy specimens or tissue aspirates from skin lesions should be put into infusion broth with 1% glucose and incubated in air or in 5–10% carbon dioxide at 35–37°C (Weaver, 1985). At 24-h intervals, subcultures to blood agar plates should be made. No visible growth occurs

on potato or MacConkey's medium. Use of selective media is not necessary unless the specimen is heavily contaminated with other bacteria such as those from soil, manure, or animal tissues (Wood, 1965; Wood and Packer, 1972). Many selective media have been described, including medium ESB (*Erysipelothrix* selective broth), a nutrient broth containing horse serum, kanamycin, neomycin and vancomycin (Wood, 1965), and a tryptose blood agar containing crystal violet and sodium azide (Packer, 1943). Another selective liquid enrichment for *E. rhusiopathiae* contains kanamycin, crystal violet, sodium azide, and liquified phenol (Bohm, 1971). A solid medium that is a modification of this enrichment contains water blue (aniline blue) and sucrose (Bohm, 1971). Since *E. rhusiopathiae* does not ferment sucrose, colonies appear colorless on the water blue sucrose agar. In cases of chronic infection in which the number of bacteria is small, enrichment by the addition of horse, calf or swine serum in broth and incubation for longer than 10 days may be necessary.

Selective Media for Erysipelothrix Modified ESB Medium (Wood, 1965)

Nutrient broth no. 2 (Oxoid) dehydrated	25 g
Distilled water	1 liter
Horse serum	50 ml
Kanamycin	400 mg
Neomycin	50 mg
Vancomycin	25 mg

Place specimen in 10 ml of modified ESB medium and incubate overnight at 35°C. Remove 5 ml, centrifuge at 1400×g for 20 min, resuspend the sediment in 1-2 ml of 0.8% saline, and plate a sample on MBA medium. After incubation at 35°C for 24–48 h, examine the plate for colonies.

MBA Medium (Harrington and Hulse, 1971)

Heart infusion agar (Difco)	40 g
Sodium azide	0.4 g
Distilled water	1 liter
Horse blood or	20 ml
Horse serum	50 ml

Packer's agar (Packer, 1943) is recommended for grossly contaminated specimens such as feces or soil because it is more selective for *E. rhusiopathiae* than is MBA medium (Jones, 1986).

Phenotypic identification of the organism is based on the results of Gram stain, lack of motility, hydrogen sulfide production, indole production, catalase activity, growth on agar containing potassium tellurite, and hemolysis on blood agar. The result of any one test is insufficient for identification. *Erysipelothrix rhusiopathiae* will need to be differentiated from other Gram-positive bacilli, in particular from *Actinomyces* (*Corynebacterium*) *pyogenes* and *Arcanobacterium*

(*Corynebacterium*) *haemolyticum*, and from *Listeria monocytogenes*. These other organisms are β-hemolytic on blood agar and do not produce hydrogen sulfide in the butt of TSI slants. *Listeria monocytogenes* is catalase positive and motile. The neomycin susceptibility test can be used to distinguish *E. rhusiopathiae* from *Listeria monocytogenes*, the former being resistant to neomycin and the latter being susceptible (Fuzi, 1963). Some *Bacillus* species and streptococci form hydrogen sulfide, but they can be differentiated from *E. rhusiopathiae* by formation of spores and by cellular morphology, respectively. *Erysipelothrix rhusiopathiae* has occasionally been misidentified as a viridans streptococcus (Procter, 1965; Gorby and Peacock, 1988). It has also been dismissed as a contaminant.

The mouse protection test is considered the best method for confirming an isolate as *E. rhusiopathiae* (Jones, 1986). In this test, a subcutaneous injection of 0.1 ml from an 18- to 24-h broth culture of the suspected *E. rhusiopathiae* is administered to mice along with a dose of commercial equine hyperimmune *E. rhusiopathiae* antiserum at another site. A control group of mice is injected with the broth culture but not the antiserum. If the organism is *E. rhusiopathiae*, the mice that did not receive antiserum die in 5–6 days, but those receiving antiserum are protected (Weaver, 1985). This test detects only those strains that are virulent for mice, but since most strains are virulent it is a good confirmatory test. One may also inject suspect clinical material subcutaneously into mice and isolate the organism from the kidneys or spleen when they die a few days later (Ewald, 1981).

Erysipelothrix rhusiopathiae has heat- and acid-stable, type-specific antigens and heat-labile, species-specific antigens (Kalf and Grece, 1964; Grieco and Sheldon, 1970; Jones, 1986). The type-specific antigens are polysaccharides. Strains may be identified serologically. In 1949, Dedié proposed that the two main serovars be designated as "A" and "B" and that strains which showed no reaction with A- or B-type-specific antiserum be designated as "N." New serovars in group N were designated by consecutive letters of the alphabet. One of the problems with this system was that different serological methods were used. Kucsera (1973) recommended the use of a double agar-gel diffusion precipitin test using autoclaved antigens and type-specific antisera and a uniform system for designating serovars using Arabic numbers. This numerical system is preferred over the older alphabetical system. Serovars 1 and 2 correspond to A and B of Dedié's system. These are the most common of the 22 serovars (Wood et al., 1978; Norrung, 1979). Strains of human and animal origin are

antigenically alike (Sneath et al., 1951). Most virulent strains causing acute infection belong to serovar 1 (or A). Strains of serovar 2 (or B) have been isolated primarily from chronic cases.

Direct and indirect fluorescent-antibody tests are also available in lieu of the mouse protection test to confirm identification of *E. rhusiopathiae* (Avilag et al., 1972; Heggers et al., 1974). They can be used to detect *E. rhusiopathiae* in tissues (Dacres and Groth, 1959; Seidler et al., 1971) and in enrichment broth (Harrington et al., 1974). In general, serological tests are not practical for routine use in a clinical laboratory for identification of the organism or for detection of antibody in patient sera. Bacteriophages active on *E. rhusiopathiae* strains have been isolated (Valerianov et al., 1976).

Identification schemes for *Erysipelothrix* strains, especially in comparison with other rapidly and aerobically growing Gram-positive rods, coryneforms and streptococci have been published by von Graevenitz and Funke (1996), Soto et al. (1994), and Freney et al. (1992). Potential errors in the recognition of *E. rhusiopathiae* have been summarized by Dunbar and Clarridge (2000).

The original seven *E. tonsillarum* strains studied (Takahashi et al., 1987a; 1987b) originated from pigs raised on different farms in different locations in Japan. Strains were cultivated on BI broth culture and BI agar (pH 7.6). Phenotypically strains of this species resemble those of *E. rhusiopathiae*. However, the virulence (measured by LD_{50}; the dose that kills 50% of the population) for mice is usually higher for *E. rhusiopathiae* strains ($1.0–25 \times 10^0$) than for *E. tonsillarum* strains (1.0×10^0 to 6.9×10^5). All but one *E. tonsillarum* strain in the study of Takahashi et al. (1987a) were serotype 7, showed no erythema at skin injection sites, and were nonsystemically pathogenic.

Erysipelothrix inopinata was isolated as a contaminant in a vegetable based growth medium. In the course of validating production processes involved in industrial aseptic manufacture of pharmaceuticals, a vegetable based growth medium was tested for its effect on dilution performance. Dehydrated CSB medium (peptone vegetable, 20.0 g; D(+)-glucose, 2.5 g; K_2HPO_4, 2.5 g) was added to 1 litre distilled water and the solution filtered through a membrane filter (pore width, 0.2 μm). A medium sample incubated at room temperature for 3 days became turbid. Microscopic analysis and plating in medium TSA (tryptic soy agar: casein peptone, 15 g; soy peptone, 5 g; NaCl, 5.0 g; agar 15.0 g; and water, 1 liter, pH.7.3) and TSS (TSA + 5% sheep blood) indicated the presence of a single contaminant, DSM 15511[T].

MOLECULAR IDENTIFICATION Analysis of the 16S rRNA gene sequence will allow unambiguous affiliation of an isolate to the genus. The high sequence similarity found for *E. rhusiopathiae* and *E. tonsillarum*, however, will not allow the affiliation to either of these species. Identification of members of the genus *Erysipelothrix* has been proposed on the basis of a polymerase chain reaction (PCR) system, using a selective primer pair that amplifies a 407-bp DNA segment of the 16S rRNA gene (Makino et al., 1994). In silico analysis of the 16S rRNA gene sequence of *E. inopinata* indicates that this species too will be identified (Verbarg et al., 2004). Another PCR system has been described for the amplification of the rDNA gene cluster of *Erysipelothrix rhusiopathiae* and *E. tonsillarum* (Takeshi et al., 1999). PCR amplification was able not only to distinguish between the two species but also to discriminate between strains of serovar 2, 13 and 18.

Affiliation of strains to described species by DNA-DNA hybridization studies has been published by Takahashi et al. (1992).

Analysis of nucleic acid patterns has been performed by low molecular mass RNA fingerprinting (Collins-Thompson et al., 1991), pulsed-field gel electrophoresis (Ahrne et al., 1995; Okatani et al., 2001), and automated ribotyping, carried out with the RiboPrinter microbial characterization system (Qualicon; DuPont). The RiboPrint pattern of confirmed the 16S rRNA gene similarities between *E. rhusiopathiae* and *E. tonsillarum* and the more separate position of *E. inopinata* (Verbarg et al., 2004).

At the protein level, various methods have been applied in the discrimination of *Erysipelothrix* strains, including computerized comparison of proteins (Bernath et al., 1997; Bernath et al., 2001), sodium dodecylsulfate (SDS) gel electrophoresis of whole cell proteins (Tamura et al., 1993), multilocus enzyme electrophoresis (Chooromoney et al., 1994), and enzymatic profiling (Takahashi et al., 1989).

ANALYSES OF GENES OTHER THAN RRNA GENES Table 4 compiles sequenced non-*rrn* genes and oligonucleotides, targeting medically relevant genes, some of which are patented but their accession numbers and sequences indicated in public databases (e.g., EBI EBI is the European Bioinformatics Institute, Cambridge, UK (www.ebi.uk.uk)). Other genes, such as housekeeping genes, can be used to construct phylogenetic trees or included in multi-locus-sequence analyses.

Table 4. Examples of genes other than *rrn* genes sequenced from *Erysipelothrix* spp.

Gene sequenced	Comment	Patent or accession number	References
E. rhusiopathiae protective antigen	Collecting and purification	JP2002034568[a]

CHAPTER 1.2.14

The Genus *Gemella*

MATTHEW D. COLLINS

Introduction

The genus *Gemella* until recently consisted of two species, *G. haemolysans* (the type species of the genus), and *G. morbillorum* (Berger, 1992). In the past few years four other species, *G. bergeri* (Collins et al., 1998b), *G. sanguinis* (Collins et al., 1998a), *G. palaticanis* (Collins et al., 1999) and *G. cuniculi* (Hoyles et al., 2000), have been assigned to the genus. The cells of gemellae are cocci, which are arranged in pairs, tetrads, small irregular clusters and sometimes in small chains; elongate and rod-shaped forms may also occur. Cells stain Gram positive but often decolorize easily and appear Gram negative. The organisms are facultatively anaerobic, preferring an atmosphere rich in CO_2, but growth can occur under both aerobic and anaerobic conditions (Berger, 1992). Gemellae are nonmotile and do not form endospores. They are cytochrome oxidase- and catalase-negative.

The genus *Gemella* was originally monospecific, containing only *G. haemolysans*. Because the organism was easily decolorized, it was originally classified as a species of the genus *Neisseria* by Thjøtta and Bøe (1938). These workers recovered the organism from the sputum of a patient with chronic bronchitis, and it was named *N. haemolysins* because of its hemolytic behavior on rabbit blood. The species however phenotypically differed markedly from other members of the *Neisseria* genus, and Berger therefore created the genus *Gemella* (meaning "a little twin") to accommodate the species (Berger, 1960b; Berger, 1961).

Originally *Gemella* was proposed as an aerobic, oxidase-negative, catalase-negative genus within the family Neisseriaceae, but its high sensitivity to penicillins and its resistance to aminoglycosides and polymyxins were more consistent with an affinity to the Gram-positive streptococci (Berger, 1960a). Later studies by Reyn et al. unequivocally showed *G. haemolysans* was incompatible with the family Neisseriaceae (Reyn et al., 1966; Reyn et al., 1970). Electron microscopy studies showed *G. haemolysans* possessed a Gram-positive type cell wall and its DNA G+C content was found to be lower than those of true *Neisseria* species and other genera within the *Neisseriaceae*. Consequently *Gemella* was included in the family Streptococcaceae in the 8th edition of *Bergey's Manual of Determinative Bacteriology* (Reyn, 1974). Later Stackebrandt et al. (1982), on the basis of 16S rRNA cataloguing studies, found *G. haemolysans* neither to be related to Neisseriaceae nor to Streptococcaceae but formed an individual line of descent among the low DNA G+C content Gram-positive bacteria.

A second species, *G. morbillorum*, was added to the genus *Gemella* by Kilpper-Bälz and Schleifer (1988). This organism was first isolated using anaerobic culture methods from patients with measles (Tunnicliff, 1917) and named "*Diplococcus rubeolae*" (Tunnicliff, 1933). This name was subsequently withdrawn (Tunnicliff, 1936) and Prévot's epithet for the same organism, *Diplococcus morbillorum*, was adopted. The species was transferred to the genus *Peptostreptococcus*, as *Peptostreptococcus morbillorum* by Smith (1957), and later Holdeman and Moore (1974) considered the species to be an anaerobic to aerotolerant streptococcus, and reclassified the species as *Streptococcus morbillorum*. Facklam and colleagues observed the close morphological and physiological similarity between *S. morbillorum* and *G. haemolysans* and considered these organisms to be synonyms (Facklam and Smith, 1976; Facklam, 1984). Berger and Pervanidis (1986) also found *S. morbillorum* and *G. haemolysans* were physiologically closely related, but since the cells of both species divide in two planes at right angles, they considered this precluded their assignment to the *Streptococcus* genus. *Streptococcus morbillorum* was finally transferred to the genus *Gemella* on the basis of physiological and phylogenetic evidence (Kilpper-Bälz and Schleifer, 1988), a placement confirmed by comparative 16S rRNA sequencing (Whitney and O'Connor, 1993). In the past few years, four other new species have been assigned to the *Gemella* genus viz, *G. bergeri* and *G. sanguinis* from human clinical sources (Collins et al., 1998a; Collins et al., 1998b) and *G. palaticanis* and *G. cuniculi* from animals (Collins et al., 1999; Hoyles et al., 2000). It is now known that all six

Gemella species form a robust rRNA cluster within the low G+C *Clostridium* subphylum, and do not display a particularly close phylogenetic affinity with any described Gram-positive, catalase-negative genus (Collins et al., 1999; Hoyles et al., 2000). A tree showing the phylogenetic relationships of gemellae and their nearest relatives is shown in Fig. 1.

Habitats

Gemella haemolysans and *G. morbillorum* are commensals of the mucous membranes of humans and some other warm-blooded animals. Although the habitat of the other two *Gemella* spp. from humans, *G. bergeri* and *G. sanguinis*, are not known, it seems likely that they occupy similar niches. *Gemella haemolysans* has been isolated from the oral cavity and the upper respiratory tract of healthy people. The organism has been recovered from the nasopharyngeal mucosa of 25–30% of people sampled (Berger and Wezel, 1960c; Berger, 1985). It has also been recovered from human dental plaque (de Jong and van Hoeven, 1987) and the intestines of pigs (Molitoris et al., 1986). *Gemella morbillorum* is also found in the human oral cavity and upper respiratory tract (Kannangara et al., 1981; Kolenbrander and Williams, 1983; Dzink et al., 1984). In addition, *G. morbillorum* is also found in the human intestinal tract where it is reported to represent approximately 0.1% of the total viable count (Holdeman et al., 1977). Like *G. haemolysans*, it has also been found in the intestinal contents of pigs (Molitoris et al., 1986).

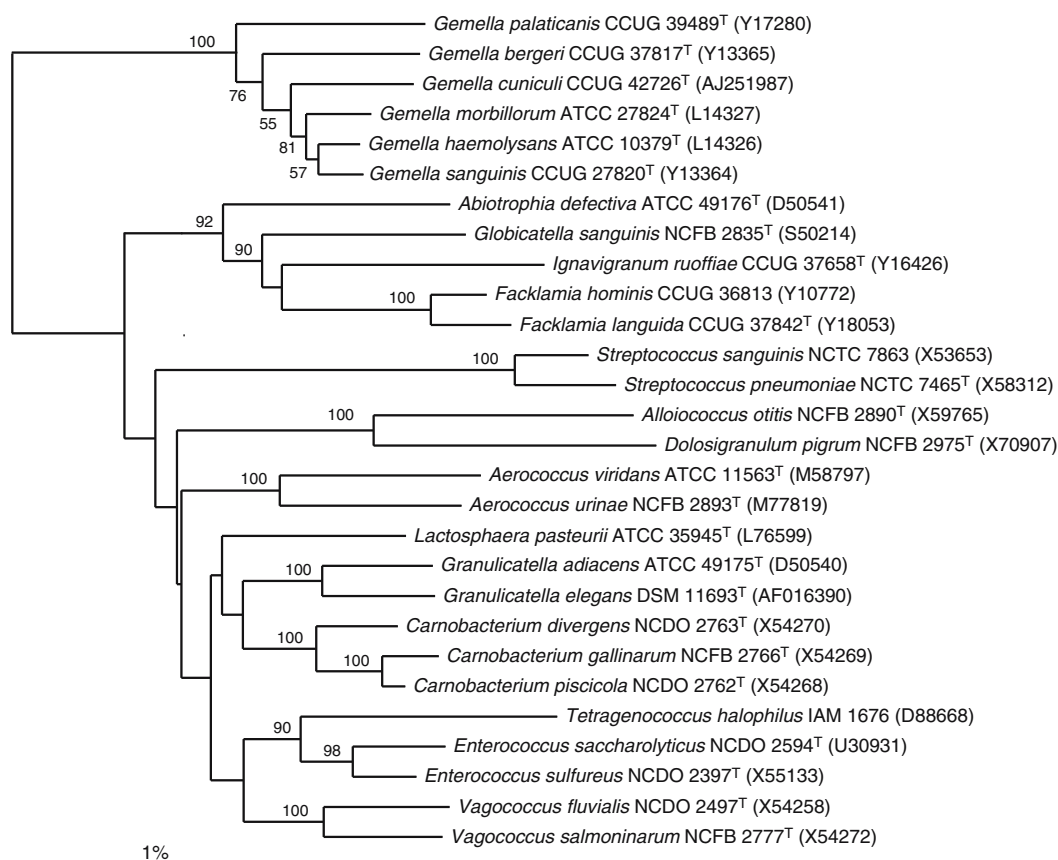
Little is known about the distribution of the more recently described *Gemella* species. Both *G. bergeri* and *G. sanguinis* have been isolated from human clinical sources, including from blood cultures of patients with subacute bacterial endocarditis (Collins et al., 1998a; Collins et al., 1998b). The only known source of *Gemella palaticanis* is the oral cavity of a dog (Collins et al., 1999), whereas *G. cuniculi* was originally recovered from a submandibular abscess of a rabbit (Hoyles et al., 2000).


Fig. 1. Dendrogram showing the phylogenetic interrelationships of *Gemella* species based on 16S rRNA gene sequences. The tree was constructed using the neighbor-joining method. Bootstrap re-sampling values, expressed as percentages of 500 replications, are given at the branching points.

Isolation and Maintenance

Gemella species can be grown on blood agar. With the exception of *G. morbillorum*, *Gemella* species should be incubated in the presence of oxygen (with or without additional CO_2), but for the growth of *G. morbillorum*, oxygen should be excluded (Berger and Pervanidis, 1986). While incubation in elevated CO_2 concentrations stimulates the growth of gemellae, the aerotolerant *G. morbillorum* prefers an anaerobic atmosphere.

For isolating *G. haemolysans* from oropharyngeal swabs, organisms should be streaked onto blood agar, where they form smooth, non-hemolytic or α-hemolytic colonies that resemble viridans streptococci. The hemolytic reaction, an important characteristic in the presumptive identification of *G. haemolysans*, depends on the nature of the growth medium (choice of blood and agar base). β-Hemolysis is only consistent on Mueller-Hinton agar supplemented with rabbit blood. This is the best-suited medium for the isolation of colonies suspected of being *G. haemolysans*. For isolating *G. haemolysans* from septicemic infections, freshly drawn blood can be transferred to commercially available blood culture media, and incubated aerobically or anaerobically. Generally, the liquid medium becomes slightly turbid after 3 days, after which culture fluid can be streaked onto blood (rabbit, sheep or horse) agar plates. The isolation of *G. haemolysans* from cerebrospinal fluid (CSF) can be achieved by streaking out a small amount of CSF deposit onto blood agar (Mitchell and Teddy, 1985). *Gemella haemolysans* has also been recovered from dental plaque (see de Jong and van der Hoeven [1987] for a detailed description of the method).

Gemella morbillorum has been recovered from a broader range of clinical sources than *G. haemolysans*. The organism can be isolated from swabs and pus by plating onto blood (usually 5% defibrinated sheep blood) agar plates. The minute colonies of are generally either non-hemolytic or are surrounded by a zone of α-hemolysis (greening; Holdeman and Moore, 1974; Facklam, 1977). Hemolysis may or may not be influenced by blood source (Facklam and Wilkinson, 1981; Berger and Pervanidis, 1986). Hemolysis may also be influenced by the strain, presence/absence of oxygen and CO_2 levels. In *G. morbillorum*, hemolysis is not a constant character. *Gemella morbillorum* can be recovered from dental plaque; samples are transferred to thioglycolate broth (Difco) containing 20% beef infusion, and dilutions streaked onto Columbia blood agar incubated in an atmosphere containing H_2, CO_2 and N_2 (1:1:8; Kolenbrander and Williams, 1983). *Gemella morbillorum* has been

isolated from the human intestinal tract using rumen-fluid-glucose-cellobiose agar (RGCA) used for culturing anaerobes (Moore and Holdeman, 1974; Holdeman et al., 1976).

During laboratory work, gemellae can be routinely maintained on a variety of agar media, such as heart infusion agar, Mueller-Hinton agar (Difco, BBL), trypticase soy agar (BBL), and Columbia agar (Biomerieux), supplemented with blood (5–7%), serum (5–10%) or ascitic fluid (10–20%). Plates can be incubated aerobically (with or without additional CO_2). Newly isolated *G. morbillorum* strains, which are not yet adapted to these conditions, should be cultured anaerobically. The growth of *G. morbillorum* may be improved by the addition of 0.001% pyridoxal-HCl to the blood agar. Heart infusion, brain heart infusion, and trypticase soy broths enriched with serum or ascitic fluid serve as suitable liquid media. For *G. morbillorum*, Todd-Hewitt broth supplemented with 0.001% pyridoxal-HCl is a good medium, as is thioglycolate broth supplemented with 10% serum for *G. haemolysans*.

For short-term preservation, *G. haemolysans* can be streaked onto heart infusion agar slants with 10% ascitic fluid or 10% inactivated serum added, or stabbed into the medium, incubated for 1 day, and then kept at room temperature (Berger, 1992). *Gemella morbillorum* has been preserved in chopped meat-glucose broth at room temperature (Kannangara et al., 1981). *Gemella morbillorum* has been maintained on trypticase soy agar containing 5% sheep blood (Dzink et al., 1984) in an atmosphere of N_2, H_2 and CO_2 (8:1:1).

For long-term preservation, *Gemella* strains can be maintained in media containing 15–20% glycerol stored at –70°C, or lyophilized.

Identification

The identification of *Gemella* can be achieved using either morphological and biochemical criteria or by molecular taxonomic methods. All 6 species possess characteristic 16S rRNA gene sequences, and sequence analysis is probably the quickest and most reliable tool for speciation (Collins et al., 1999; Hoyles et al., 2000). However, identification to the species level in routine laboratories can also be achieved by phenotypic methods.

On blood-based agars, gemellae grow slowly forming small, circular, entire, low convex, translucent to opaque, smooth (occasionally mucoidal) colonies that somewhat resemble viridans streptococci. Some strains of gemellae are hemolytic (Berger, 1992). On trypticase soy sheep blood agar, most strains are α- or non-

hemolytic. The expression of hemolysis can depend on the type of blood and agar base used. Wide zone (β) hemolysis may be observed with some strains, especially *G. haemolysans*, on blood agar bases containing rabbit blood. *Gemella morbillorum* produces greening or fails to hemolyze the blood, although exceptional strains of this species may display wide zone hemolysis. Examination for β-hemolysis is best performed on Mueller-Hinton agar supplemented with rabbit blood (Berger, 1992).

Cellular morphology can be helpful in differentiating gemellae from streptococci. Gemellae divide in two planes, generally at right angles to each other. Cells are cocci arranged in pairs, often with adjacent sides flattened, or arranged in tetrads, small irregular clusters or short chains. Pleomorphism may be observed. Morphology varies with strain and cultural conditions (Berger, 1992). Size of the cells may vary considerably; diameter varies from about 0.5 μm to more than 1 μm and "giant cells" have been observed (Berger, 1992). In *G. morbillorum*, pleomorphism may be very pronounced, coccal forms are frequently elongate, and cells may be of unequal size. Elongate cells are generally 0.5 by 1.2 μm (Holdeman and Moore, 1974), but longer cells (up to 2–3 μm) have been reported (Prévot, 1933). Gemellae possess a Gram-positive cell wall type but may appear Gram-variable owing to their relatively rapid decolorization with alcohol. Though of the Gram-positive type, their walls are relatively thin (10–20 nm; Reyn et al., 1970; Mills et al., 1984), which probably accounts for their Gram-variable character. Electron microscopic studies have revealed the cells of *G. haemolysans* are surrounded by a "corona" of floccular or fibrous material arranged radially at the cell surface (Reyn et al., 1966; Reyn et al., 1970). An outer layer of similar structure has also been observed in *G. morbillorum* (Mills et al., 1984). It is thought that the fibrous material in *G. morbillorum* is a polyanionic polysaccharide, which is extensively cross-linked.

The optimum growth temperature of gemellae is probably 35–37°C, but species can grow over a wider range of temperatures. They do not grow at 10 or 45°C or in broth containing 6.5% NaCl. They are bile esculin negative. Gemellae are catalase and oxidase negative; they are fermentative, producing acid from glucose and some other carbohydrates. The major end products of anaerobic glucose metabolism by *G. haemolysins* and *G. morbillorum* are L-lactic and acetic acids (Brooks et al., 1971; Holdeman and Moore, 1974; Stackebrandt et al., 1982); formic acid is also detected in both species. Under aerobic conditions, the end products of glucose metabolism formed by *G. haemolysans* are equimolar amounts of acetate and CO_2 (Stackebrandt et al., 1982). The presence of fructose-1,6-bisphosphate aldolase indicates that *G. haemolysans* degrades glucose by the Embden-Meyerhof pathway (Stackebrandt et al., 1982). Acid formation in carbohydrate broth by *Gemella* species, using conventional tests, can be somewhat varied with some substrates. Acid is produced from mannitol and sorbitol by some *Gemella* strains, but these can be variable characteristics depending on the test method. Using the API rapid ID 32Strep system, *G. sanguinis*, *G. cuniculi* and most strains of *G. morbillorum* ferment these substrates, whereas *G. haemolysans* and *G. palaticanis* do not. Some strains of *G. bergeri* produce acid from mannitol but fail to ferment sorbitol. *Gemella haemolysans*, *G. morbillorum*, *G. palaticanis* and *G. sanguinis* produce acid from maltose and sucrose, whereas *G. bergeri* and *G. cuniculci* do not. *Gemella palaticanis* produces acid from lactose, whereas other gemellae fail to ferment this substrate. Using the same API test system, none of the *Gemella* species produce acid from D-arabitol, L-arabinose, cyclodextrin, glycerol, melibiose, melezitose, methyl-β-D-glucopyranoside, pullulan, raffinose, ribose or tagatose. Gemellae do not hydrolyze esculin, gelatin, hippurate or urea. They do not degrade casein or liquefy coagulated serum. None of the *Gemella* species reduce nitrate. However the reduction of nitrite appears to be a regular characteristic of *G. haemolysans* but not of *G. morbillorum* (Berger, 1992). It is not known whether the other four *Gemella* species reduce nitrite. Some species produce acid and alkaline phosphatases. Activity for both of these enzymes, are detected in *G. cuniculi*, *G. haemolysans* and *G. sanguinis* using the API rapid ID 32Strep and API ZYM systems, but not in the other species. Most *Gemella* strains are pyrrolidonyl arylamidase positive; the only known isolate of *G. cuniculi* is pyrrolidonyl arylamidase negative. All gemellae are arginine dihydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, α-mannosidase, α-fucosidase, lipase C14, trypsin, *N*-acetyl-β-glucosaminidase, and valine arylamidase negative.

Numerous biochemical tests are potentially useful in differentiating the various *Gemella* species, but some of these vary according to the test method used. There is sometimes poor correlation between results obtained by conventional methods and miniaturized test systems (such as API kits). *Gemella haemolysans* can however usually be distinguished from *G. morbillorum* by producing alkaline phosphatase and by failing to produce acid from mannitol and sorbitol. Most strains of *G. morbillorum* are alkaline phosphatase negative, and most produce acid from mannitol and sorbitol (Berger, 1961; Berger and Pervanidis, 1986). *Gemella sanguinis* and *G.*

Table 1. Characteristics useful in distinguishing species of the genus *Gemella*.

	G. bergeri	*G. cuniculi*	*G. haemolysans*	*G. morbillorum*	*G. palaticanis*	*G. sanguinis*
Acid from:						
Lactose	−	−	−	−	+	−
Mannitol	d	+	−	d	−	+
Maltose	−	−	+	+	+	+
Sorbitol	−	+	−	d	−	+
Sucrose	−	−	+	+	+	+
Trehalose	−	−	−	−	+	−
Production of:						
PAC	−	+	+	−	−	+
PAL	−	+	+	−	V	+
APPA	d	−	−	d	+	+
GTA	−	−	d	−	+	−
VP test	−	−	−	−	−	+

Symbols: +, present in all strains; −, absent in all strains; d, present in some strains; and V, variable.
Abbreviations: PAC, acid phosphatase; PAL, alkaline phosphatase; APPA, alanyl phenylalanine proline arylamidase; GTA, glycyl tryptophan arylamidase; and VP, Voges-Proskauer.
Tests performed using API rapid ID32 Strep system except for production of PAC, which is performed using API ZYM kit.

bergeri, also associated with human clinical sources, can be readily distinguished from each other and the aforementioned species biochemically using the API rapid ID 32Strep system. *Gemella sanguinis* is similar to *G. morbillorum* in forming acid from mannitol and sorbitol but differs from the latter species in producing alkaline phosphatase. Similarly, *G. bergeri* differs from *G. haemolysans*, *G. morbillorum* and *G. sanguinis* by failing to produce acid from maltose and sucrose (Collins et al., 1998b). It further differs from *G. haemolysans* and *G. sanguinis* by being alkaline phosphatase negative (Collins et al., 1998a). Tests useful in distinguishing between the various *Gemella* species, using the API rapid ID 32Strep system, are shown in Table 1.

The DNA G+C content of *G. haemolysans*, *G. bergeri*, *G. morbillorum*, *G. palaticanis* and *G. sanguinis* are 33.5 ± 1.6 (by the buoyant density [Bd] method), 32.5 (by the melting temperature [T_m] method), 30 (T_m), 32 (T_m), and 31 (T_m) mol%, respectively. The cell wall murein of *G. morbillorum* is of the L-Lys-Ala$_{1-3}$ type (Kilpper-Bälz and Schleifer, 1988). There is no information on the murein composition of the other *Gemella* species.

Antimicrobial Susceptibility

Knowledge of the antimicrobial susceptibilities of species of the genus *Gemella* is somewhat fragmentary (Buu-Hoi et al., 1982; Berger, 1992). Both *G. haemolysans* and *G. morbillorum* are highly sensitive to penicillins, cephalosporins, tetracyclines, chloramphenicol and lincomycins. *Gemella haemolysans* is strongly inhibited by macrolide antibiotics (erythromycin, spiramycin and oleandomycin), vancomycin, ristocetin, novobiocin and tyrothricin. Some strains are however resistant to erythromycin and tetracycline. A majority of strains are also inhibited by bacitracin and fusidic acid. *Gemella haemolysans* is resistant to sulfonamides and trimethoprim and also displays low-level resistance to aminoglycosides (streptomycin, kanamycin, gentamycin, tobramycin, amikacin and neomycin). Synergy between penicillin G and either gentamycin or streptomycin, and between vancomycin and the aforementioned aminoglycosides is also observed (Buu-Hoi et al., 1982). The antimicrobial susceptibility patterns of *G. haemolysans* and *G. morbillorum* are typical of Gram-positive organisms and resemble those of viridans streptococci. *Gemella bergeri* and *G. sanguinis* are sensitive to vancomycin, but their susceptibilities to other antimicrobials remain unknown. There is no information on the susceptibilities of *G. palaticanis* and *G. cuniculi* to antibiotics.

Clinical Significance

Gemella haemolysans and *G. morbillorum*, like many other commensal bacteria of the human microbiota, are opportunistic pathogens. Both species are capable of causing severe localized and generalized infection, particularly in immunocompromised patients (Durak et al., 1983; Etienne et al., 1984; Mitchell and Teddy, 1985; Eggelmeier et al., 1992; Petit et al., 1993; Pradeep et al., 1997).

Gemella haemolysans has been isolated from blood cultures of patients with endocarditis (Buu-Hoi et al., 1982; Chatelain et al., 1982; Blin et al., 1984; Laudat et al., 1984; Kaufhold et al., 1989; Brack et al., 1991; Morea et al., 1991; Fresard et al., 1993). The organism has also

been isolated from CSF cultures of patients with meningitis (Mitchell and Teddy, 1985; Aspevall et al., 1991; May et al., 1993; Petit et al., 1993).

Gemella morbillorum are infrequent clinical isolates, but nevertheless it is clear that this species can participate in serious human infections. Owing to the regular recovery of *G. morbillorum* from the blood and throat of measles patients, this organism was mistakenly believed to be the causative agent of the disease (Tunnicliff, 1917; Tunnicliff, 1933; Duval and Hibbard, 1927). Prévot et al. (1967) reported *G. morbillorum* from various suppurative processes, including dental abscess, tonsillitis, axillary hydroadenitis, pleuritis, lung abscess, peritonitis, subphrenic abscess, and pyelonephritis. Facklam (1977) recovered *G. morbillorum* from blood, respiratory, genitourinary, wound and abscess (including one isolate from brain abscess) specimens. In his study of over 1200 viridans streptococci from clinical sources, *G. morbillorum* constituted more than 3% of the strains. *Gemella morbillorum* has since been recovered from blood cultures of patients with endocarditis (e.g., Durak et al., 1983; Etienne et al., 1984; Coto and Berk, 1984; Maxwell, 1989; Omran and Wood, 1993) and from a variety of other sources such as from cultures of synovial fluid from septic arthritis (Von Essen et al., 1993), from CSF cultures from patients with meningitis (Debast et al., 1993) or brain abscess (Murray et al., 1998).

There is very little information about the possible clinical significance of other *Gemella* species. Both *G. bergeri* and *G. sanguinis* have been isolated from human clinical specimens including from blood cultures of persons with bacterial endocarditis (Collins et al., 1998b; Collins et al., 1998a; Shukla et al., 2002). It is possible that *G. bergeri* and *G. sanguinis* are responsible for a similar range of conditions as those due to *G. haemolysans* and *G. morbillorum*. Indeed owing to difficulties encountered in identifying *Gemella* species and limitations in tests often used in routine laboratories, it seems likely that these organisms may have been misidentified as *G. haemolysans* and/or *G. morbillorum* in the past. Of the remaining *Gemella* species, *G. palaticanis* was originally isolated from the oral cavity of a dog (Collins et al., 1999), whereas the only known strain of *G. cuniculi* was recovered, in mixed culture, from a submandibular abscess of a rabbit (Hoyles et al., 2000). There is currently no evidence that these species cause disease.

CHAPTER 1.2.15

The Genus *Kurthia*

ERKO STACKEBRANDT, RONALD M. KEDDIE AND DOROTHY JONES

Introduction

In 1883, H. Kurth published the description of *Bacterium zopfii*, which he had isolated from the intestinal contents of chickens (Kurth, 1883). Two years later, Trevisan (1885) created the genus *Kurthia* with *K. zopfii* as the type species. However, over the ensuing years Kurth's organism was given a variety of generic names, including *Zopfius* (Wenner and Rettger, 1919); the valid name *Kurthia* really came into general use only after the publication of the seventh edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1957). The genus *Kurthia* contains three species, *K. zopfii*, *K. gibsonii* (Keddie and Shaw, 1986), and *K. sibirica* (Belikova et al., 1986). Additional species are mentioned in the literature but have not been validated, e.g., "*Kurthia catenaforma*" (Kato et al., 1972), "*Kurthia bessonii*" (Pancoast et al., 1979) or "*Kurthia variabilis*" (Severi, 1946).

Reference strains are *K. zopfii* DSM {20580}^{T} (NCIB {9878}^{T}, NCTC {10597}^{T}); *K. gibsonii* DSM {20636}^{T} (NCIB {9858}^{T}, ATCC 43195^{T}); *K. sibirica* DSM {4747}^{T} (VKM {V-1549}^{T}, CCM {3477}^{T}).

Kurth isolated the organism now called "*K. zopfii*" by streaking material from the intestinal contents of chickens onto nutrient gelatin plates. When the plates were incubated, the organism grew out from the original streak and through the gelatin in long, fine, apparently branched threads. For a number of years following the original isolation, *K. zopfii* aroused considerable interest because of its characteristic growth patterns in nutrient gelatin, and various attempts were made to explain the observed phenomena. Most characteristic is the appearance in a gelatin slant. If the slant is inoculated with a single central streak and incubated in the near vertical position, then the resultant growth resembles a bird's feather (Boyce and Evans, 1893; Zikes, 1903; Sergent, 1906; Sergent, 1907; Jacobsen, 1907; Kufferath, 1911). The outgrowths, which appear to follow the lines of stress in the gelatin, are presumably a result of the organism's marked filament-forming ability coupled with an inability to hydrolyze gelatin; both motile and nonmotile strains exhibit this phenomenon (Keddie, 1949).

In the few decades following its original isolation, *K. zopfii* (or *K. zenkeri*, a synonym of *K. zopfii*) was isolated from a variety of sources, including fresh and putrefied meat (Günther, 1896; Jacobsen, 1907; Wenner and Rettger, 1919), wastewater and air from abattoirs (Jacobsen, 1907), preserved sausage (Günther, 1896), and pus from a cat's ear (Boyce and Evans, 1893). It was also reported to occur in feces (Flügge, 1896), water (Flügge, 1896; Migula, 1900), and to be common in milk (Orla Jensen, 1921). One strain of an organism considered to be *K. zopfii* was isolated from air at an altitude exceeding 3,000 m (10,000 ft) (Proctor, 1935). A nonvalidated strain of "*Kurthia bessonii*" has been isolated from a variety of clinical materials (Liebschers et al., 1965; Pancoast et al., 1979), but there is no evidence of pathogenicity in authentic members of the genus.

Following this early interest in *K. zopfii*, the genus *Kurthia* received scant attention for many years, but the more recent rediscovery that *K. zopfii* and the organism now called "*K. gibsonii*" frequently occur as components of the aerobic flora of meats and meat products once again focused attention on the genus. However, bacteria of the genus *Kurthia* do not appear to have been implicated directly in the spoilage process of meats and meat products.

Bacteria of the genus *Kurthia* are strictly aerobic, Gram-positive rods that do not produce acid from glucose. Consequently, in earlier studies they were sometimes considered to be taxonomically related to one or more of the aerobic genera of coryneform bacteria. Indeed, some earlier numerical taxonomic surveys seemed to support this view (see Shaw and Keddie, 1983a). The tentative inclusion of *Kurthia* in the section on the "Coryneform Group of Bacteria" in the eighth edition of *Bergey's Manual of Determinative Bacteriology* was interpreted as supporting this similarity (e.g., see Ludwig et al., 1981), and presumably led to the inclusion of the chapter on "The Genus *Kurthia*" in the section on "The Coryneform Bacteria" in the first edition of "*The Prokaryotes*" (Starr et al., 1981). However,

chemical studies of the peptidoglycan structure (Schleifer and Kandler, 1972), isoprenoid quinone composition (Collins et al., 1979), polar lipid composition (Goodfellow et al., 1980), and the G+C content of the DNA (Belikova et al., 1980; Belikova et al., 1986; Shaw and Keddie, 1984) distinguish *Kurthia* from members of the "coryneform group."

Phylogenetic Position

The results of early rRNA oligonucleotide sequencing studies of *Kurthia zopfii* ATCC 6900 and various Gram-positive bacteria confirm that *Kurthia* is only very distantly related to the aerobic coryneform bacteria and is more closely related to members of the genera *Bacillus*, *Lactobacillus*, *Staphylococcus* and *Streptococcus* (Ludwig et al., 1981). This taxonomic placement was supported by the results of a numerical taxonomic study (Shaw and Keddie, 1983a), which showed a close phenotypic similarity between *Kurthia* and some aerobic *Bacillus* spp. but little similarity with various genera of aerobic coryneform bacteria.

Analyses of low molecular weight RNA profiles of various bacteria, *Kurthia*, and related Gram-positive organisms with a low DNA G+C content (Collins-Thompson et al., 1991) demonstrated that the pattern of *K. zopfii* and *K. gibsonii* were identical and similar to those of members of *Brochothrix* and *Listeria*. However, bacilli were not included in that study.

From 1984 on, the phylogenetic position of *Kurthia* and certain other nonsporeforming aerobic spherical and rod-shaped Gram-positive organisms was fully elucidated on the basis of rRNA cataloguing but mainly of almost complete 16S rRNA gene sequences. Unexpectedly, members of *Filibacter* (Clausen et al., 1985), *Sporosarcina*, *Planococcus* and *Marinococcus* (Farrow et al., 1992), as well as *Kurthia*, *Caryophanon*, *Planococcus* and *Exiguobacterium* (Farrow et al., 1994) were found to be closely related to members of the genus *Bacillus* (Stackebrandt et al., 1987; Ash et al., 1991; Stackebrandt and Swiderski, 2002). The genus *Bacillus* itself was found to contain several remotely related phylogenetic branches, many of which are today described as individual genera, including among others *Paenibacillus* (Ash et al., 1993), *Alicyclobacillus* (Wisotzkey et al., 1992), *Alicyclobacillus* and *Brevibacillus* (Shida et al., 1996), *Virgibacillus* (Heyndrickx et al., 1998) and *Geobacillus* (Nazina et al., 2001). The core genus of *Bacillus* still forms a phylogenetically broad cluster, consisting of different groups (Ash et al., 1991), one of which, the *Bacillus* group 2, embraces the round spore-forming bacilli (e.g.,

B. sphaericus, *B. insolitus*, and *B. silvestris*) and their nonsporeforming relatives (Stackebrandt et al., 1987).

The type strains of the three *Kurthia* species form a tight phylogenetic cluster sharing 95.8–97.7% 16S rRNA gene sequence similarity (Fig. 1). The branching is supported by high bootstrap values. *Kurthia* species are closely related to the type strains of two *Bacillus* species, i.e., *B. pycnus* JCM 11075[T] and *B. neidei* JCM 11077[T] (94.2–96.2%). The low bootstrap values indicate that the stability of their branching is less significant and may change with the inclusion of other sequences in the database. These five species form a sister clade of a cluster consisting of species of *Bacillus*, *Sporosarcina*, *Filibacter* and *Planococcus*. The hallmark of cluster 2 is the presence of either L-lysine or ornithine at position 3 of the peptide side chain of peptidoglycan. D-Glutamic acid or D-aspartic acid form the interpeptide bridge (Fig. 1). This composition is significantly different from the amino acid composition of the type species *Bacillus subtilis* and its many relatives, which contain a directly linked peptidoglycan containing *meso*-diaminopimelic acid as the diagnostic amino acid. It thus appears that the formation of round spores or loss of spores, differences in cell wall composition, and morphological variations are reflections of an individual evolutionary path of organisms of *Bacillus* group 2 that may lead to the recognition of one or more new genera, depending on the taxonomic evaluation of these differences (Rheims et al., 1999).

Genes other than those coding for 16S rRNA have rarely been sequenced. An example is the suite of eleven biotin biosynthesis genes involved in the stepwise synthesis of biotin from an unknown precursor via the pimeloyl-CoA pathway in *Kurthia* sp. DSM 10609 (Kiyasu et al., 2001; accession numbers [{www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AB045873}{AB045873}], [{www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AB045873}{AB045873}], and [{www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AB045875}{AB045875}]). The lack of the *bioW* gene, coding the pimeloyl-CoA synthetase suggest that unlike in *Bacillus subtilis* and *B. sphaericus*, pimelic acid does not serve as the precursor; the presence of the *bioC* and *bioH* genes makes it likely that a modified pathway via acetyl-CoA is used, similar to the one found in *Escherichia coli*.

Besides a chitinase gene of *K. zopfii* (accession number [{www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=D63702}{D63702}]), the *cpn60* (chaperonin 60) gene has been partially sequenced for all three type strains of *Kurthia* (a123713, a123714 and a123716). This

Fig. 1. Neighbor-joining tree (Felsenstein, 1993) generated on the basis of 16S rRNA gene sequences showing the nearest neighbors of members of the genus *Kurthia*. Bootstrap value was calculated for 500 replicate trees. The bar corresponds to a 1% difference in nucleotide sequences.

gene has the potential to serve as phylogenetic marker (Roger et al., 1998) as well as a potentially universal target for identification (Goh et al., 2000).

Habitats

There have been few systematic studies of the occurrence of *Kurthia* spp. in natural materials. However, from the limited information available, it seems that the sources from which authentic *Kurthia* spp. are regularly isolated are meat and meat products and animal feces that have lain on soil, straw, etc., for a short time. *Kurthia zopfii* and *K. gibsonii* are associated with off-flavors and taints of fresh and cured meat products stored at elevated temperatures, and the psychrophilic *K. sibirica* is associated with refrigerated samples (Keddie and Jones, 1992).

What appeared to be the most unusual source was reported by Belikova et al. (1980), who isolated several strains of *Kurthia* from samples of the intestinal contents and stomach of the Magadan (Susuman) mammoth found preserved in the permafrost in East Siberia. Of 13 strains referred to by these authors as *K. zopfii*, four had the characters of that species, three appeared to be *K. gibsonii* and the remainder were psychrophilic strains that differed from both these species (see Keddie and Shaw, 1986). A new species,

K. sibirica, was created for the psychrophilic strains (Belikova et al., 1986). While we obviously cannot comment on the ability of *Kurthia* to survive for several thousand years in permafrost, we are nevertheless certain that the highly aerobic *Kurthia* would be unable to multiply in the highly anaerobic environment of the animal gut. A solution to the problem became apparent when it was revealed that after the mammoth was removed from the permafrost it was kept in an unfrozen state for several days before examination (Belikova et al., 1986). Presumably the carcass became contaminated with *Kurthia* which then multiplied during storage. Indeed, more recent studies (see above) strongly suggest that Kurth's original isolates came from chicken intestines that had been stored at room temperature for a few days; like the mammoth, contamination with *Kurthia* (possibly from flies) would have been followed by multiplication during storage.

Meat and Meat Products

Keddie (1949) isolated *K. zopfii* and the organism now called "*K. gibsonii*" from a variety of samples of fresh meat, fat, etc., and from meat that was allowed to putrefy at room temperature. These organisms were also readily isolated from meat, fat, wastewater, etc. from an abattoir, thus confirming the early report of Jacobsen (1907).

According to Holzapfel (1992), saprophytic Gram-positive bacteria, e.g., *K. zopfii* and *K. gibsonii*, are probable minor groups belonging to the initial microbial population on the surface of meat (from healthy animals) kept in the abbatoir environment. Among other Gram-positive bacteria, *Kurthia* spp may be involved in spoilage of fresh and processed meat (Gardner, 1969; Keddie, 1981).

Ingram (1952) found that Gram-positive, non-sporeforming rods constituted about 10% of the aerobic flora of internally tainted, cured pork legs. Some of these rods were considered to be *Kurthia* spp. Also, *Kurthia zopfii* and *K. gibsonii* have been isolated from pork and pork products (Gardner et al., 1967b; Shaw and Keddie, 1983a), various ground fresh meat products (Gardner, 1969; Shaw and Keddie, 1983a), from an eviscerated, polyethylene-wrapped chicken stored at 15°C until off-flavors developed, from an irradiated lamb carcass stored for about 7 weeks at 1°C (quoted by Gardner, 1969), and from spoiled British sausages (Dowdell and Board, 1971).

Information on the numbers of *Kurthia* in these various meat products is sparse. Gardner (1969) noted that although members of the genus were regularly isolated from fresh, comminuted meat products, they usually accounted for only up to 10% of the total aerobic count. On the other hand, in six samples of pork stored at 16°C for 5 days in gas-impermeable film, gas-permeable film, or with no film, *Kurthia* represented 12–44, 9–76, and 5–69%, respectively, of the total aerobic flora but were not detected in similar samples stored at 2°C for 14 days (Gardner et al., 1967b). Holzapfel (1992) indicated growth and survival parameters for temperature between 5 and 45°C, for pH between 5.0 and 8.5, and for a_w of ca. 0.95. From these and other observations (Gardner and Carson, 1967a), Gardner (1969) concluded that *Kurthia* could compete favorably with other aerobic spoilage bacteria in meat stored at about 16°C, but not in meat stored at refrigeration temperatures. The two strains isolated by D'Aubert et al. (1975) from refrigerated, vacuum-packed meat and identified by them as *Kurthia* spp. did not have the characteristics of the genus.

Animal Feces in Contact with Soil, Straw, and Other Materials

In our experience, *Kurthia* can regularly be isolated from the feces of certain domestic animals provided it has lain on soil, straw, etc., for a short time. Keddie (1949) was unable to isolate *Kurthia* from the cecal contents of chickens or from the freshly voided feces, but three of nine samples of chicken feces that had lain on the soil for some time yielded the organism. *Kurthia zopfii* and *K. gibsonii* have been isolated from many different samples of soil-contaminated chicken feces and from various situations in poultry houses (Shaw and Keddie, 1983a). Strivastava et al. (1972) also reported the isolation of two presumptive *Kurthia* strains from a poultry house and a hatchery. Also, pig feces contaminated with straw or soil have yielded *K. zopfii* and *K. gibsonii*, as have similarly contaminated feces of horses and cows (Shaw and Keddie, 1983a).

Clinical Sources

Several strains of presumptive *Kurthia* spp. have been isolated from various clinical sources and most frequently from the feces of patients suffering from diarrhea. Some organisms were considered to be "*K. bessonii*" or "*K. variabilis*," neither of which was included in The Approved Lists of Bacterial Names (Skerman et al., 1980) and are therefore not legitimate species.

Frequently, the descriptions of the isolates mentioned contain apparently contradictory statements (e.g., facultative anaerobes; do not ferment sugars) or are too limited to be able to judge whether the organisms were indeed authentic kurthias.

Severi (1946) isolated what he considered to be a new species, "*K. variabilis*," from feces in a case of mild food poisoning. Elston (1961) isolated three strains identified as "*K. bessonii*" from a pilonidal cyst, sputum, and a diarrheal stool, and Faoagali (1974) isolated a presumptive *Kurthia* sp. from a routine eye swab. Jarumilinta et al. (1976) isolated presumptive *Kurthia* spp. from the upper intestinal tract of six of 25 patients suffering from acute diarrhea, but only from one of 24 control patients. More recently Yang et al. (1985) isolated an organism they identified as *K. zopfii* from the blood of an infant with septicemia. However, in all of these cases, the connection between the occurrence of the presumptive *Kurthia* spp. and the clinical condition was, at most, tenuous.

Other Sources

The isolation of presumptive *Kurthia* spp. has been reported from sources as diverse as "sloughing spoilage" of ripe olives ("*K. bessonii*"; Patel and Vaughn, 1973), the gut of a crab ("*K. variabilis*"; Saha and Raychaudhuri, 1973), wet-stored wood (Berndt and Liese, 1973), and from dental plaque of beagle dogs (*Kurthia*?; Wunder et al. 1976); but like those from clinical sources, the accuracy of identification of many of these isolates is doubtful.

However, more recent evidence supports the early statement by Orla Jensen (1921) that *K. zopfii* may occur in milk because this species was found at levels of about 10^4/ml in some samples of bulked, cold-stored (7°C) raw milks (C. M. Cousins, personal communication). The spoilage effect of *Kurthia* strains on fresh milk and fresh vegetables must be considered with skepticism (Gardner, 1969). *Kurthia zopfii* has occasionally been isolated from soil and surface waters (Shaw and Keddie, 1983a) and a few observations indicate that organisms resembling *Kurthia* but distinct from the accepted species occur in certain peats, namely, low-moor peat (Janota-Bassalik, 1963) and Antarctic peat (Baker and Smith, 1972).

To our knowledge *Kurthia* spp. have not yet been exploited in any biotechnological process.

Isolation

Kurthia zopfii and *K. gibsonii* may be isolated by using methods that exploit their unusual cultural properties. One of the most successful is a gelatin streak method similar to that used by Kurth and the early investigators (Keddie, 1949). However, a simple agar streak technique is a useful additional method (see Keddie, 1981).

These methods were not used for isolation of *K. sibirica*, but the report that strains of this species produce a "bird's feather" growth on nutrient gelatin (Belikova et al., 1986) suggests that they might be successful if a suitably low incubation temperature is chosen.

Gelatin Streak Method for Isolating *Kurthia* (Keddie, 1949)

A nutrient gelatin medium (YNG) of the following composition is used.

YNG Medium

Meat extract (Lab-Lemco powder, Oxoid)	4 g
Peptone (Difco)	5 g
Yeast extract (Difco)	2.5 g
NaCl	5 g
Gelatin (BDH)	60 g

Dissolve ingredients in distilled water and dilute up to 1 liter. Adjust pH to 7.0. For quantities up to 100 ml, sterilize at 115°C for 30 min. Pour plates with about 20 ml of molten YNG medium and allow to solidify in the refrigerator. Inoculate plates heavily with a single central streak of the material to be examined (or with a suspension or macerate of solid material in a small amount of sterile water). Incubate plates at 20°C with the lids uppermost and examine daily. The gelatin is usually soon liquefied around the streak, but in successful cultures, filamentous

outgrowths appear beyond this zone in 2–3 days, and after 3–4 days, a tangled mass of filaments may completely permeate the solid part of the medium if it is not completely liquefied. To obtain a pure culture, streak a small piece of gelatin containing outgrowths on yeast extract-nutrient agar medium (YNA). YNA is similar to YNG but is solidified with agar instead of gelatin.

The composition of the nutrient gelatin medium used is important, and the concentration and brand of gelatin used is particularly important; not all brands allow the typical outgrowths. The medium should be inoculated with a reference strain of *K. zopfii* (NCIB 9878) to test its ability to allow good outgrowth production. The gelatin manufactured by the BDH Chemical Co., Poole, England, is satisfactory but with some batches a higher concentration than that stated (up to 100 g/liter) may be required. Although all *Kurthia* strains tested grow well in YNB (i.e., YNG medium without gelatin), medium YNG prepared with some batches of gelatin has given poor growth. Dissolving the constituents of YNG in mineral base E (Owens and Keddie, 1969) to give MYNG (Shaw and Keddie, 1983a) overcomes this problem. When MYNG is autoclaved, a precipitate (which should be dispersed before pouring plates) is produced; the precipitate does not interfere with isolation. Overgrowth with fungi may be a problem with some materials. This can be prevented by adding nystatin (Squibb) to the molten YNG to a concentration of 10 units/ml before pouring plates.

The above-mentioned isolation procedure is not strictly selective and one should watch for filamentous or feathery growth in gelatin media, of "medusa" head appearance of young colonies under low magnification, and rhizoid growth or granular appearance on YNA (Keddie and Jones, 1992). Other bacteria that may produce outgrowths in gelatin similar to those of *Kurthia* are certain chain-forming *Bacillus* species, particularly *B. cereus* subsp. *mycoides*, although they may liquefy gelatin.

The agar streak method may be used in addition to that described above and can give successful results when rapid liquefaction of gelatin has prevented isolation of *K. zopfii* by the gelatin streak method.

Agar Streak Method for Isolating *Kurthia* (see Keddie, 1981)

The YNA Medium

Meat extract (Lab-Lemco powder, Oxoid)	4 g
Peptone (Difco)	5 g
Yeast extract (Difco)	2.5 g
NaCl	5 g
Agar	15 g

Dissolve ingredients in distilled water and dilute up to 1 liter. Adjust pH to 7.0. Inoculate the YNA medium with a single, central streak as described above. At daily intervals, examine the edge of the streak under low power (100×) of the microscope for the characteristic skeinlike outgrowths of *K. zopfii* grown on agar. Obtain pure cultures by picking carefully from the edge of the outgrowths and plating on YNA as before.

A partial enrichment of *K. gibsonii* may be achieved by preparing a preliminary enrichment in YNB incubated for 24 h at 45°C; a second subculture at 45°C is then made before inoculating and incubating YNG and YNA plates as described above. *Bacillus* spp. do not usually interfere in this modification of the method.

Isolation by Direct Plating

If they form a sufficiently high proportion of the population, *Kurthia* spp. may be isolated by direct plating on YNA (or similar media) of materials such as meat and meat products (Gardner, 1969). Surface colonies of *Kurthia* spp. are recognized by their rhizoid form (Fig. 2a) and by the typical "medusa-head" appearance of young colonies when examined at low magnification. Such colonies have a skein-like structure that is resolved into whorls with whiplike outgrowths at the edge.

It should be noted that when pure cultures are streaked on YNA, a proportion of the colonies that develop may have a granular appearance instead of the typical rhizoid form (Keddie, 1949). Therefore, it is possible that when isolating *Kurthia* from natural materials, some may be missed because they produce nonrhizoid colonies. Isolates are then examined for the characteristic properties of *Kurthia*; useful screening tests are colony form, morphology and Gram reaction, production of "bird's feather" growth on nutrient gelatin slants (Fig. 2b), and aerobic growth in glucose nutrient agar shake cultures.

Preservation of Cultures

Cultures on YNA or nutrient agar slants should remain viable for at least 6 months when stored at room temperature (about 20°C), provided that they are not allowed to dry out. Longer-term preservation (over 10 years) may be achieved by freezing on glass beads at –60 to –70°C (Jones et al., 1984). Cultures can also be preserved by freeze drying (lyophilization).

Identification

Identification as a *Kurthia* sp. may be made on the basis of the following features. Gram-
Fig. 2. (a–b) Kurthia zopfii (NCBI {9878}). (a) Rhizoid colony on yeast nutrient agar after 4 days incubation at 25°C.; Bar = 10 mm. (b) Yeast nutrient gelatin slant showing "bird's feather" type of growth; incubated 5 days at 20°C. (c–d) *Kurthia zopfii* (isolate): edge of colony on yeast nutrient agar incubated at 25°C. (c) After 24 h, showing long filaments composed of rods. (d) After 3 days, showing development of coccoid forms. Bar = 10 μm.

positive, regular, unbranched rods with rounded ends, about 0.8×3–$8 \ \mu m$ or longer, in long chains in exponential phase cultures (Fig. 2c) giving rise to coccoid cells, formed by fragmentation of the rods (Fig. 2d) or in some strains giving rise to short rods in stationary-phase cul-

tures. Strains which have been maintained in artificial culture for some time often give rise to short rods in stationary phase cultures (Shaw and Keddie, 1983a). The rods are usually motile by numerous peritrichous flagella, but nonmotile strains are known; they do not form endospores. Surface colonies on yeast nutrient agar are usually rhizoid (but granular colonial variants occur; Fig. 2a) and have a "medusa-head" appearance under low magnification (100×). They are obligate aerobes and do not form acid from glucose or other carbohydrates in peptone media. In gelatin slant cultures (see medium YNG above) inoculated with a single central streak, the growth resembles a bird's feather (Fig. 2b); the gelatin is not liquefied. They are catalase positive and grow best in the range of 25–30°C (*K. zopfii* and *K. gibsonii*) or 20–25°C (*K. sibirica*) at neutral pH.

Kurthia spp. give negative responses in most of the usual biochemical tests, e.g., indole, nitrate reduction; urease, lecithinase production; and hydrolysis of starch and esculin; however, some strains produce H_2S weakly (Jones, 1975; Shaw and Keddie, 1983a). The peptidoglycan type is A4α (L-lysine-D-aspartic acid; Belikova et al., 1980; Shaw and Keddie, 1984), abbreviated A11.31 (Schleifer and Kandler, 1972). The major isoprenoid quinones in *K. zopfii* and *K. gibsonii* are unsaturated menaquinones with seven isoprene units (MK-7; Collins et al., 1979). The peptidoglycan composition and the major fatty acids in all three species are based upon the L-Lys-D-Asp type and straight-chain saturated, *anteiso-* and *iso*-methyl-branched chain acids, respectively: the major fatty acid is 12-methyltetradecanoic (*anteiso*-$C_{15:0}$) acid in *K. zopfii* and *K. gibsonii* (Goodfellow et al., 1980), but with 13-methyltetradecanoic (*iso*-$C_{15:0}$) acid in addition in *K. sibirica* (Belikova et al., 1986). The polar lipids in *K. zopfii* and *K. gibsonii* are diphosphatidylglycerol, phosphatidylglycerol and phosphatidylethanolamine (Goodfellow et al., 1980). The G+C content is remarkably constant among isolates of all three species and lies in the range of about 36–38 mol% (Belikova et al., 1980; Belikova et al., 1986; Shaw and Keddie, 1984). Glucose is not used as a carbon + energy source, but acetate appears to be utilized by most strains of all three species (Shaw and Keddie, 1983a; Belikova et al., 1986). When supplied with a suitable source of amino acids, all species require B vitamins (Shaw and Keddie, 1983b; Belikova et al., 1986). For other characters of *K. zopfii* and *K. gibsonii*, see Table 1.

Bacteriophages isolated from *K. zopfii* are morphologically identical with the short-tailed, elongated head phages of the GA-1 species of *Bacillus* phages (Rocourt et al., 1983). The activity of these phages on *K. gibsonii* and *K. sibirica* is not known.

There is, to our knowledge, no published information on the presence of plasmid DNA in *Kurthia* spp., but a recent study demonstrated plasmid DNA in the type strain *K. zopfii* (NCTC {10597}). Further, the range of plasmids of this strain was identical to that of two isolates from sausages identified as *Brochothrix thermosphacta* (C. E. R. Dodd, personal communication). Although this observation suggests plasmid exchange between the genera, confirmation of such a phenomenon would require the demonstration of molecular identity between the plasmid complements.

Differentiation of *Kurthia* spp.

DNA-DNA hybridization studies of a few strains (some atypical) support the conclusion reached in the numerical taxonomic study of Shaw and Keddie (1983a) that *K. zopfii* and *K. gibsonii* are distinct species. Cherevach et al. (1983) showed that the yellow strains now included in the species *K. sibirica* are genomically distinct from both *K. zopfii* and *K. gibsonii*, as DNA-DNA reassociation values were low (20% with *K. zopfii* and 40% with *K. gibsonii*). These results confirm the moderate 16S rRNA gene sequence similarity among the type strains of the three species (95.8–97.6%; see phylogenetic position). The three species may be distinguished by using the characters listed in Table 2. It should be noted, however, that Shaw and Keddie (Shaw and Keddie, 1983a; Shaw and Keddie, 1983b; Shaw and Keddie, 1984) described a number of strains that had most or all of the characters of the genus *Kurthia* as defined by Keddie and Rogosa (1974), but could not be assigned to a species.

Those taxa most likely to be confused with *Kurthia* are the catalase-positive, nonsporulating Gram-positive *Brochothrix thermosphacta*, *Listeria* spp. and certain *Bacillus* spp. The organisms are easily distinguishable by a range of phenotypic properties (Table 3). *Brochothrix thermosphacta* (Sneath and Jones, 1976) is very similar to *Kurthia* in morphological features (see Davidson et al., 1968) but is nonmotile, facultatively anaerobic, and produces acid by fermentation from glucose and various other carbohydrates.

Confusion with some aerobic, saprophytic coryneform bacteria is possible but is much less likely. On nutrient agar certain chain-forming *Bacillus* spp. may give colonies somewhat similar to *K. zopfii* and have a similar morphology in exponential-phase cultures. They may also give outgrowths in nutrient gelatin, although such growth is usually, if not always, followed by liquefaction. They may be distinguished by endospore formation (detected by a test of heat resistance following growth on nutrient agar supplemented with Mn^{+2} [2 μg/ml] for at least 7

Table 1. Other features of *K. zopfii* and *K. gibsonii*.[a]

Characteristics	*K. zopfii*	*K. gibsonii*	Characteristics	*K. zopfii*	*K. gibsonii*
Acid from			Carbon + energy source, cont'd:		
Butan-1-ol	d	+	Citrate	–	d
Pentan-1-ol	d	d	Pyruvate	+	d

From Holzapfel (1992).

coryneform bacteria, the rods are irregular in form, may show rudimentary branching, and commonly occur in V formations but never in chains.

The cellular fatty acid composition has been used as an aid to the identification of some asporogenous, aerobic Gram-positive rods (Bernard et al., 1991). Still treated as members of the coryneform group of organisms, the two strains of *Kurthia* could be distinguished from strains of *Listeria*, *Rothia*, *Jonesia*, *Oerskovia* and *Propionibacterium* by the predominance of *i*-$C_{15:0}$ over the second predominant fatty acid *ai*-$C_{15:0}$.

A molecular approach has been used to discriminate members of *Listeria* from *Kurthia zopfii* ATCC 33403 (Edmond et al., 1993). A cloned rrn operon probe, consisting of the 3′ terminus of the 16S rRNA gene, the spacer element and the 5′ terminus of the 23S rRNA gene of *Listeria monocytogenes* was found to be genus-specific under stringent conditions in dot blot analyses as well in a heteroduplex nucleic acid enzyme-linked immunoabsorbent assay.

CHAPTER 1.2.16

The Genus *Bacillus*—Nonmedical

RALPH A. SLEPECKY AND H. ERNEST HEMPHILL

History

One of the earliest bacteria to be described was "*Vibrio subtilis*" by Ehrenberg in 1835. In 1872, Cohn renamed the organism *Bacillus subtilis* (Gordon, 1981). That organism was a charter member of a large and diverse genus, initiated by Cohn, that is part of the family Bacillaceae. This family's distinguishing feature is production of endospores, which are round, oval, or cylindrical highly refractile structures formed within bacterial cells. Spores were first described by Cohn in *subtilis* and later by Koch in the pathogen, *B. anthracis* (the only major pathogen of vertebrates in the genus). Cohn demonstrated the heat resistance of spores of *B. subtilis* and Koch first described in *B. anthracis* the developmental cycle of sporeformers, vegetative cell to spore and spore to vegetative cell (Keynan and Sandler, 1983). For the reasons of unusual spore resistance to chemical and physical agents; the developmental cycle; ubiquity of its members; and *B. anthracis* pathogenicity, the genus *Bacillus* attracted early interest which has continued since.

The endospore, either as the free spore or as the structure within the vegetative cell, in which case the whole entity is referred to as a sporangium, is readily detected using the phase contrast microscope (see Fig. 1). This is because the spore at a point in the life cycle (to be detailed later) becomes highly refractile. Early workers used stains and special conditions (such as prolonged heating) to colorize the chemically impermeable spore (Doetsch, 1981). However, a Gram-stain is sufficient to determine the presence of spores because the spore remains unstainable while the vegetative cells or the vegetative part of the sporangia will stain. Because of this ease of microscopic detection of the spore and its heat resistance, many different endosporeformers can be easily found. Using any habitat—soil, water, food, etc.—as the source, sporeformers can be readily isolated by suspending a sample in water and heating at 80°C for 10 to 30 min. Vegetative cells and other resting forms such as cysts and exospores are usually killed at that temperature. The heat-resistant endospore can then be plated on appropiate media and isolates recovered in 24 to 48 h. An idea of the kinds of habitats from which *Bacillus* species have been isolated can be obtained from Table 1. Heating the inoculum, when used in conjunction with cultivation at different temperatures, hydrogen ion concentrations, degrees of aeration, and substrates, has resulted in isolating many different species of endosporeformers. The media used for the isolation and cultivation of *Bacillus* species are listed in Table 2.

More often than not since the discovery of bacteria (and in every case since 1913), the possession of an endospore has been used as a premier characteristic in keys for the classification of bacteria. The family Bacillaceae was first formulated by Fisher in 1895 (Gordon, 1981). The features of the members of the genus *Bacillus* that distinguish it from other Bacillaceae (all endosporeformers) are their aerobic nature, which may be strict or facultative, rod shape, and catalase production. The other genera of sporeformers include *Sporolactobacillus*, which is microaerophilic and catalase-negative; *Clostridium*, anaerobic but does not reduce sulfate; *Desulfotomaculum*, anaerobic but does reduce sulfate; *Sporosarcina*, a coccus; and *Thermoactinomycetes*, which while forming endospores displays typical actinomycete characteristics.

General Taxonomic Considerations

Like the sirens of Greek mythology enticing the unsuspecting sailors, *Bacillus* species have captured the curiosity of many microbiologists. The first 107 years of the efforts to classify and identify members of the genus *Bacillus* is chronicled by R.E. Gordon (1981) who with her colleagues (Gordon et al., 1973; Smith et al., 1946, 1952) made many significant contributions on which the current classification (Claus and Berkeley, 1986) was built. The early attempts were "on

This chapter was taken unchanged from the second edition.

Fig. 1. *B. megaterium* sporeforming cells as seen in the phase contrast (A) or in the interference contrast (B) microscope. The refractile bodies in the center are the spores. Bar = 5 μm.
Table 1. Origins of isolates of *Bacillus* species.

Name of *Bacillus* species	Habitats from which isolated
B. subtilis	Soil, water
B. acidocaldarius	Thermal acid water and soil
B. alcalophilus	pH 10 enrichment from soil
B. alvei	Soil, diseased bee larvae
B. amylolyticus	Soil
B. anthracis	Anthrax-diseased animals
B. azotoformans	Soil
B. badius	Feces, foods, marine sources
B. brevis	Soil, foods
B. cereus	Soil, foods
B. circulans	Soil
B. coagulans	Acid foods
B. fastidiosus	Soil, poultry litter
B. firmus	Soil, salt marshes
B. globisporus	Soil, water
B. insolitus	Soil
B. larvae	Diseased bee larvae
B. laterosporus	Soil, water
B. lautus	Soil, feces
B. lentimorbus	Diseased honeybee larvae
B. lentus	Soil, foods
B. licheniformis	Soil
B. macerans	Plant materials, food
B. macquariensis	Subantarctic soil
B. marinus	Marine sediment
B. megaterium	Soil
B. mycoides	Soil
B. pabuli	Soil, fodder
B. pantothenicus	Soil
B. pasteurii	Soil, water, sewage
B. popilliae	Diseased scarabid beetles
B. psychrophilus	Soil, water
B. pumilus	Soil
B. schlegelii	Lake sediment
B. sphaericus	Soil, water sediments, foods
B. stearothermophilus	Soil, hot spring, foods
B. thermoglucosidasius	Soil
B. thuringiensis	Soil, foods
B. validus	Soil

Based on Claus and Berkeley (1986).

rocky shoals" because a classification based on only the two characteristics of aerobic growth and endospore formation resulted in grouping together many bacteria possessing different kinds of physiology and occupying a variety of habitats. This heterogeneity in physiology, ecology, and genetics makes it difficult to categorize the genus or to make generalizations about it. The range of physiological life styles is impressive: degraders of most all substrates derived from plant and animal sources including cellulose, starch, proteins, agar, hydrocarbons, and others; antibiotic producers; heterotrophic nitrifiers; denitrifiers; nitrogen fixers; iron precipitators; selenium oxidizers; oxidizers and reducers of manganese; facultative chemolithotrophs; acidophiles; alkalophiles; psychrophiles, thermophiles and others (Slepecky, 1972; Norris et al., 1981; Claus and Berkeley, 1986) (see Table 2). Because of this vast diversity of physiological types, our knowledge of sporeformer ecology is slight (Slepecky, 1972; Norris et al., 1981; Slepecky and Leadbetter, 1977, 1984). In the main, sporeformers as part of the zymogenous flora of the soil are viewed as opportunists. Upon access to the proper germinants and substrates for subsequent outgrowth, they will actively contribute to and participate in the various microhabitats which make up the soil's heterogeneous environment. Aerial distribution of the dormant spores may explain the occurrence of *Bacillus* species in most habitats examined. This diversity was apparent even with classical phenotypic characterizations based primarily on morphology (particularly size and position of the endospore within the vegetative cell), nutrition; growth characteristics; and various substrate utilization and physiological assessments.

At one time, 145 species made up the genus (Gordon, 1981). The understanding of the genus has been improved by augmenting the phenotypic characterizations with measurements of the DNA base composition and DNA-DNA hybridigation. Currently, there are listed in *Bergey's*

Table 2. Media used for the isolation and cultivation of *Bacillus* species.

B. acidocaldarius	Part A: $(NH_4)_2SO_4$, 0.4; $MgSO_4$, 1.0; $CaCl_2 \cdot 2H_2O$, 0.5; KH_2PO_4, 6.0; distilled H_2O, 1 liter; pH adj. to 4.0 Part B: glucose, 2.0; yeast ext., 2.0 distilled H_2O, 1 liter Combine A and B after sterilization
B. alcalophilus	Part A: glucose, 1.0; peptone, 5.0; yeast ext., 5.0; KH_2PO_4, 10.0 $MgSO_4 \cdot 7H_2O$, 0.2, distilled H_2O, 900ml. Part B: $Na_2CO_3 \cdot 10H_2O$, 20; distilled H_2O, 100ml. Combine A and B after sterilization (final pH = 10.5)
B. azotoformans	Peptone, 10.0; $Na_2HPO_4 \cdot 12H_2O$, 3.6; $MgSO_4 \cdot 7H_2O$, 0.03; $MnSO_4 \cdot H_2O$, 0.05; KH_2PO_4, 1.0; NH_4Cl, 0.5; $CaCl_2 \cdot 2H_2O$, 0.1; distilled H_2O, 1 liter.
B. brevis	K_2HPO_4, 0.2; $MgSO_4 \cdot 7H_2O$, 0.02; NaCl, 0.02; $FeSO_4 \cdot 7H_2O$, 0.01; $MnSO_4 \cdot H_2O$, 0.01; betaine, betaine·HCl or valine, 0.05M; agar, 16.0; distilled H_2O, 1 liter.
B. fastidiosus	K_2HPO_4, 0.8; KH_2PO_4, 0.2; $MgSO_4 \cdot 7H_2O$, 0.05; $CaCl_2 \cdot 2H_2O$, 0.05; $FeSO_4 \cdot 7H_2O$, 0.015; $MnSO_4 \cdot H_2O$, 0.01; uric acid, 10.0; distilled H_2O, 1 liter.
B. lentus	Peptone, 10.0; meat ext., 10.0; agar, 15.0; distilled H_2O, 1 liter. adj. pH to 7.0–7.5; after sterilization, add 100g urea, steam for 10min.
B. licheniformis	Peptone, 5.0; meat ext., 3.0; KNO_3, 80.0; distilled H_2O, 1 liter; adj. pH to 7.0; fill glass-stoppered bottle to top for anaerobic conditions.
B. marinus	Peptone, 5.0; yeast ext., 1.0; $FePO_4 \cdot 4H_2O$, 0.01; agar, 15.0; aged sea water, 750ml; distilled H_2O, 250ml; adj. pH to 7.6.
B. pantothenicus	Nutrient broth + 4% (w/v) NaCl
B. pasteurii	Nutrient broth + 2% (w/v) urea
B. schlegelii	$Na_2HPO_4 \cdot 2H_2O$, 4.5; KH_2PO_4, 1.5; NH_4Cl, 1.0; $MgSO_4 \cdot 7H_2O$, 0.2; $CaCl_2 \cdot 2H_2O$, 0.01; ferric ammonium citrate, 0.005; $NaHCO_3$, 0.5; trace element soln, 5ml ($ZnSO_4 \cdot 7H_2O$, 0.1; $MnCl_2 \cdot 4H_2O$, 0.03; H_3BO_3, 0.3; $CoCl_2 \cdot 6H_2O$, 0.02; $CuCl_2 \cdot 2H_2O$, 0.001; $NiCl_2 \cdot 6H_2O$, 0.02; $Na_2MoO_4 \cdot 2H_2O$, 0.03; distilled H_2O, 1 liter) Other: 65C, atmosphere of 0.05atm. O_2 + 0.01atm. CO_2 + 0.45atm. H_2
B. stearothermophilus	Nutrient agar; incubate cultures at 55°C

[a]Numerical amounts are grams unless specified.
[b]Most other *Bacillus* cultures will grow on nutrient broth and nutrient agar.
Based on Claus and Berkeley (1986).

Table 3. Major distinguishing characteristics of some *Bacillus* species.

Thermophile	*B. stearothermophilus*	Hydroxy aromatic compounds degrader	*B. gordonae*
	B. thermodenitrificans		
	B. caldotenax	Nitrate reduction to N_2	*B. azotoformans*
Thermophilic acidophiles	*B. coagulans*		*B. licheniformis*
	B. acidocaldarius	Growth restricted to uric acid, allantoin or allantoic acid	*B. fastidiosus*
Psychrophiles	*B. psychrophilus*	Growth at high pH and NH_4Cl	*B. pasteurii*
	B. macquariensis	Requires pantothenic acid	*B. pantothenicus*
	B. globisporus	Requires biotin	*B. pumilus*
	B. insolitus	Produces heat stable glucosidase	*B. thermoglucosidasius*
	B. psychrosaccharolyticus	Insect pathogens[a]	*B. thuringiensis*
Alkalophile	*B. alcalophilus*		*B. larvae*
Facultative chemolithotroph	*B. schlegelii*		*B. popilliae*
Nitrogen fixers	*B. polymyxa*		*B. sphaericus*
	B. macerans		*B. lentimorbus*
	B. azotofixans	Human and animal pathogen	*B. anthracis*
Alginate degraders	*B. alginolyticus*		*B. cereus*
	B. chrondrotinus		
Aromatic acid and phenol degrader	*B. benzoevorans*		

[a]See Chapter 77.

Table 4. DNA-base composition and sources of the type strains of *Bacillus* species.

Bacillus species	GC content (mol%)		Culture collection number				
	Tm[a]	BD[b]	ATCC[d]	DSM	NCIB	NCTC	NRRL
acidocaldarius	60.3	62.3	27009	446	11725		NRS1607

[a]Tm, GC content by thermal melting.
[b]BD, GC content by buoyant density.
[c]ND, not determined.
[d]ATCC, American Type Culture Collection; DSM, Deutsche Sammlung von Mikroorganismen; NCIB, National Collection of Industrial Bacteria; NCTC, National Collection of Type Cultures; NRRL, Northern Regional Research Laboratory.

Manual of Systematic Bacteriology (BMSB) 40 recognized species (Claus and Berkeley, 1986), Table 4 lists these with their GC content. There are several validly published new species shown to be genetically and phenotypically distinct from other *Bacillus* species that have not been described in *Bergey's Manual*. These include *B. pulvifaciens* (Nakamura, 1984); *B. alginolyticus* and *B. chrondrotinus*, two alginate-degrading species, (Nakamura, 1987); *B. smithii* (Nakamura et al., 1988); *B. thermoleovorans*. an obligately thermophilic hydrocarbon-utilizing organism (Zarilla and Perry, 1987); *B. benzoevorans*, an aromatic acid and phenol degrader (Pichinoty et al., 1984); and *B. gordonae*, degrader of hydroxy aromatic compounds (Pichinoty et al., 1986).

There are more than 200 species of *Bacillus* in the category "*Species Incertae Sedis*" (Claus and Berkeley, 1986). These have been inadequately described or the orginal isolates have been lost. Presumably, these can be revived for listing in *Bergey's Manual* after reisolation and more detailed studies. For example, after extensive reconsideration of phenetic and molecular data it has been proposed that *B. flexus*, *B. fusiformis*, *B. kaustophilus*, *B. psychrosaccharolyticus*, *B.*

simplex (Priest et al., 1988), and *B. thiaminolyti-cus* (Nakumura, 1989) be recognized.

The literature contains many important experiments done with *Bacillus* isolates that have not yet been properly identified to species such as: *Bacillus* sp. strain SGI, a manganese-oxidizing and reducing organism (Johannes et al., 1986; Rosson and Nealson, 1982); *Bacillus* sp. strain C-59 and *Bacillus* sp. strain N-6, both alkalophilic organisms with unusual bioenergetic properties (Kitada and Horikoshi, 1987; Kitada et al., 1989); *Bacillus* sp. strain Gx6638, a novel alkaline and heat stable serine protease-secreting strain (Durham et al., 1987); and *Bacillus* sp. strain MGA3, a thermophilic methanol-utilizing species, mutants of which are capable of producing large amounts of lysine (Guettler and Hanson, 1988; Schendel et al., 1989).

An extensive list of phenetic characters of most members of the genus have been complied and procedures for the isolation and identification of individual species have been presented (Gordon et al., 1973; Berkeley and Goodfellow, 1981; Norris et al., 1981; Claus and Berkeley, 1986). Summaries of one such rendition are shown in Tables 5 and 6 (Norris et al., 1981).

The GC content (32–69 mol%) of the known *Bacillus* species as well as DNA hybridization experiments have revealed the heterogeneity of the genus (Priest, 1981; Fahmy et al., 1985) (see Table 4). Not only is there variation from species to species but there are differences in GC content within strains of a species identified on other bases. For example, the GC content of the *B. megaterium* group ranges from 36 to 45% (Hunger and Claus, 1981). It is thus understandable

Table 5. Simplified key for the tentative identification of typical strains of *Bacillus* species.

1. Catalase: positive 2
              negative 17
2. Voges-Proskauer: positive 3
              negative 10
3. Growth in anaerobic agar: positive 4
              negative 9
4. Growth at 50°C: positive 5
              negative 6
5. Growth in 7% NaCl: positive .... *B. licheniformis*
              negative .... *B. coagulans*
6. Acid and gas from glucose (inorganic N): positive.......... *B. polymyxa*
              negative......... 7
7. Reduction of NO₃ to NO₂: positive........................... 8
              negative .... *B. alvei*
8. Parasporal body in sporangium: positive .... *B. thuringiensis*
              negative .... *B. cereus*
9. Hydrolysis of starch: positive .... *B. subtilis*
              negative .... *B. pumilus*
10. Growth at 65°C: positive .... *B. stearothermophilus*
              negative 11
11. Hydrolysis of starch: positive 12
              negative 15
12. Acid and gas from glucose (inorganic N): positive............... *B. macerans*
              negative 13
13. Width of rod 1.0μm or greater: positive .... *B. megaterium*
              negative.................. 14
14. pH in V-P broth <6.0: positive .... *B. circulans*
              negative .... *B. firmus*
15. Growth in anaerobic agar: positive....................... *B. laterosporus*
              negative 16
16. Acid from glucose (inorganic N): positive .... *B. brevis*
              negative .... *B. sphaericus*
17. Growth at 65°C: positive .... *B. stearothermophilus*
              negative 18
18. Decomposition of casein: positive............................. *B. larvae*
              negative............................. 19
19. Parasporal body in sporangium: positive .... *B. popilliae*
              negative .... *B. lentimorbus*

that Priest et al. (1981, 1988), who have conducted extensive numerical analysis of many unit characters in addition to the DNA studies, have proposed that the genus *Bacillus* be split into multiple genera, since the intrageneric heterogeneity is as great as exists in most bacterial families. Priest et al. (1988) assigned 80 organisms of species rank to five or more cluster groups. Their studies reemphasized the heterogeneity of the *B. brevis*, *B circulans*, *B. coagulans*, *B. sphaericus*, and *B. stearothermophilus* groups.

A variety of techniques have been employed to find either a simple approach to *Bacillus* taxonomy or a quick and painless identification methodology. Assessment of lipid analyses (reviewed by Minnikin and Goodfellow, 1981) indicated that *Bacillus* could not be separated into discrete groups. On the other hand, some species could be delineated from others. For example, *B. acidocaldarius* could be characterized by its menaquinone (nine isoprenoid units, MK-9), cyclohexyl fatty acids, triterpenes, and complex lipids.

Using the API System (Analytab Products Incorporated) (a rapid identification system wherein many standardized biochemical assessments can be made on test strips) and some

supplementary classical determinants, Logan and Berkeley (1981, 1984) have examined 1,075 *Bacillus* strains. They were able to show that the API System tests were more reproducible than the classical tests.

Pyrolysis gas-liquid chromatography has been applied to the problems of *Bacillus* taxonomy (O'Donnell and Norris, 1981; O'Donnell et al., 1988). Although there are still some problems with the technique, some promise for its use in classification and identification has been shown. For example, as with DNA-DNA hybridization studies, a separation has been made between *B. subtilis* and *B. amyloliquefaciens*. When gasliquid chromatography was applied to examine the subgroups of *B. megaterium*, data were obtained that confirmed the heterogeneity of the group even though there was some difficulty in resolving relationships within the group.

Shute et al. 1984 have used Curie-point pyrolysis mass spectrometry as a taxonomic tool. *B. subtilis*, *B. pumilus*, *B. licheniformis*, and *B. amyloliquefaciens* could be separated using data obtained from nonsporulating cultures (those grown on nutrient agar); however, such was not the case with cultures sporulating on nutrient agar plus manganese.

Ribosomal RNA Sequencing

The most effective approach to *Bacillus* taxonomy may be analysis of 16S rRNA molecules by oligonucleotide sequencing (Fox et al., 1977; Stackebrandt and Woese, 1979). That technique holds much promise for leading microbial taxonomy into natural phylogenetic relationships. However, traditional taxonomists may be dismayed to find that *Bacillus* species show kinship with nonsporeforming species. Early studies with this powerful tool showed a close relationship among *Bacillus*, *Planococcus*, *Sporosarcina*, *Staphylococcus*, and *Thermoactinomycetes* (Stackebrandt et al., 1987; Stackebrandt and Woese, 1981). In a recent study 16S rRNA cataloging showed that *B. subtilis* and other ellipsoidal-sporeforming species, *B. cereus*, *B. megaterium*, and *B. pumilus*, formed a coherent cluster, while the round-sporeforming species, *B. sphaericus*, *B. globisporus*, and "*B. aminovorans*" did not cluster. Furthermore, the latter group were closer phylogenetically to nonsporeforming organisms as follows: *B. sphaericus* to *Caryophanon latum*; *B. globisporus* to *Filibacter limicola*; *B. pasteuri* to *Sporosarcina urea* and "*B. aminovorans*" to *Planococcus citreus*. Cell wall composition agreed except with the last case. *B. stearothermophilus* fell outside the main *Bacillus* cluster and showed some relationship to *Thermoactinomycete vulgaris* (Stackebrandt et al., 1987).

In a more recent 16S rRNA sequencing survey, three major *Bacillus* taxonomic cluster groups were defined (Jurtshuk et al., 1989). This was accomplished by determining complete or partial sequences of 16S RNA on 35 recognized neotype reference strains or type species by the technique of Lane et al. 1985. The partial sequences analyzed typically exceeded 1,100 nucleotides. Phylogenetic analyses were performed using three different approaches (Sneath and Sokal, 1973; Fitch and Margoliash, 1967; Saitou and Nei, 1987) which showed three major groupings of *Bacillus* spp., hereinafter referred to as clusters I, II, and III (see Table 7). The 16S rRNA *Bacillus* cluster groups were quite different from those previously noted by Stackebrandt et al. (1987). This is revealed by direct comparison to the commonly used morphological groupings (see Table 7). Except for morphological group II and the Unassigned Subgroup 2E, all strains sequenced fell into the *B. subtilis* cluster I grouping. *Bacillus* strains of morphological group II fell into all three 16S rRNA cluster groups and *B. macquariensis*, unlike other psychrophiles, fell into the *B. alvei* cluster II group.

Comparative 16S rRNA analyses on thermophilic and psychrophilic *Bacillus* strains (Wisotzkey et al., 1989) showed that the thermophiles, *B. stearothermophilus*, *B. thermodenitrificans* and *B. caldotenax* formed a subgroup within the *B. subtilis* cluster but separate from both the "thermotolerant" mesophilic, *B. subtilis* and *B. licheniformis* strains, and the moderate thermophile, *B. coagulans*. The psychrophilic strains, *B. psychrophilus* and *B. insolitus*, fell into cluster I while *B. macquariensis* fell into cluster II.

Because several species were included in the current study that had previously been examined by 16S rRNA oligonucleotide cataloging, it is possible to compare the two data sets directly. As a result, it is possible to augment the membership of cluster I to include *B. fastidiosus*, *B. firmus*, *B. badius* and *B. pasteurii* (C. B. Woese, personal communication). In addition, it is extremely likely that at least two nonsporeforming strains, *Planococcus citreus* (Stackebrandt and Woese, 1979) and *Filibacter limicola* (Clausen et al., 1985), as well as *Sporosarcina ureae* (Pechman et al., 1976), are properly regarded as members of cluster I.

Table 7. *Bacillus* 16S rRNA cluster groups.

Morphological group	*B. subtilis* cluster I	*B. alvci* cluster II	*B. brevis* cluster III
I	*B. subtilis, B. cereus, B. licheniformis, B. pumilus, B. megaterium* strain Mohb, *B. coagulans, B. smithil*		
II	*B. circulans, B. larvae, B. stearothermophilus*	*B. alvei, B. polymyxa, B. macerans, B. azotofixans, B. pulvifaciens*	*B. brevis, B. laterosporus*
III	*B. sphaericus*		
Subgroup A	"*B. thiaminolyticus*," *B. alcalophilus*		
Subgroup B	*B. lentus*		
Subgroup C	*B. freundenreichii*, "*B. aneurinolyticus*"		
Subgroup D	*B. pantothenticus*		
Subgroup E1	"*B. psychrophilus*," *B. insolitus*		
Subgroup E2		*B. macquariensis*	

Table provided by Peter Jurtshuk.

Life Cycle; Sporulation and Germination as Models for Differentiation

Introduction

The processes of resting cell formation and the change back to the vegetative cell in a variety of prokaryotes (Losick and Shapiro, 1984) present excellent models for studying differentiation, with the added attendant advantages of microbial systems: ease of handling, use of large numbers of cells, fast growth, synchrony, and availability of mutants. The endospore models were recognized early and, therefore, more knowledge has been accumulated using them than with other prokaryotic systems. As the attempt to categorize the many species of *Bacillus* has had a long history, so have the efforts to unravel the many aspects of the life cycle of *Bacillus* (for a historical treatment see Keynan and Sandler, 1983). Because of the enormous literature in this area, the present treatment of the life cycle relies mainly on reviews of the subject and covers mainly highlights of germination and sporulation.

The cycle of germination, outgrowth, growth, and sporulation (shown schematically in Fig. 2) has been studied from many different aspects with many different species of spore-formers but because of the genetic versatility of *B. subtilis*, most work has focused on this species.

Germination and Outgrowth

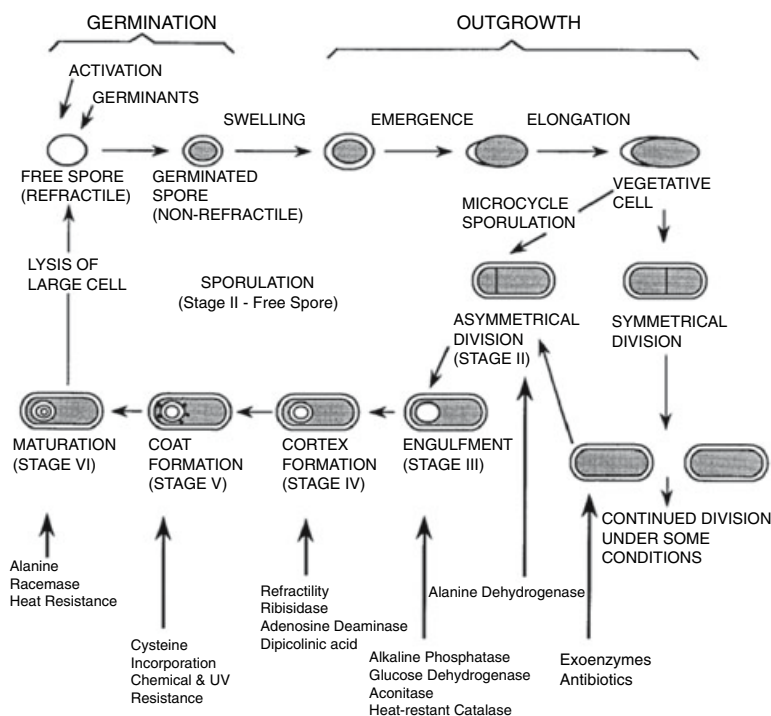
Free spores usually must be activated for germination. Activation is a reversible process which conditions the spore for germination and increases the number of spores undergoing germination as well as the rate of germination. Spores can be activated by a variety of treatments, notably exposure to heat. During activation there is a loss of some coat protein, dipicolinic acid (DPA), and Zn^{2+} along with an increase in membrane fluidity. Germination, the breaking of the spore's highly dormant state, follows (recent reviews on germination include Setlow, 1983, and Foster and Johnstone, 1989). A series of degradative reactions is triggered in an unknown manner by simple compounds such as certain amino acids and ribosides or mixtures (no universal germinant has been described) or certain nonnutrient conditions, and can be monitored by the loss of spore refractility as seen in the phase-contrast microscope and by decrease in optical density. No metabolic activity can be detected during the first 2 min of germination of spores that require alaine or glucose for germination. Generation of ATP or production of known metabolic products of these initiators has not been found. Mutants deficient in key glycolytic pathway enzymes can germinate, thus ruling out glycolysis in the case of spores requiring glucose for germination. The same spores can be germinated by nonmetabolizable glucose analogs as well. However, metabolism may play a role in the germination of *B. fastidiosus*, whose


Fig. 2. Cycle of germination, outgrowth, and sporulation of a typical sporeforming bacterium. Also shown are some biochemical and physical events associated with various stages. (modification of a figure in Slepecky, R.A. (1978)).

spores can only be germinated with uric acid, which is the main carbon source for these unique organisms (Aoki and Slepecky, 1973). One hypothesis suggests that germinants act on receptor proteins, possibly in the inner membrane, which then undergo conformational changes that alter permeability (Foster and Johnstone, 1989). This leads to an autocatalytic loss of heat resistance and to changes that initiate metabolism, leading to vegetative growth. Another view, based on the observation that inhibition of the electron transport system affects germination, postulates that respiration and ATP create a proton motive force, lending to the establishment of a proton gradient. The proton motive force is used for transport of ions from core to cortex to neutralize other ions (Gould, 1983).

Upon germination, the spores not only lose their resistance to heat but also resistance to radiation and injurious chemicals; their stainability also increases. Concomitantly with "phase" darkening, the spores swell, break out of their coats, and exude up to 30% of their dry weight; about one-half of the exudate consists of a calcium chelate of the spore-specific substance, DPA, and the remainder consists of peptidoglycan fragments (from the action of cortex lytic enzymes) and amino acids. The earliest measurable events are the loss of calcium, DPA, and heat resistance. This is followed by metabolic events using high-energy compounds produced early in germination from energy reserves stored in the dormant spore.

RNA synthesis begins rapidly within 2 min of germination. The dormant spore lacks the ability to produce amino acids and amino acid biosynthesis is absent early in germination. During the first minutes of germination, 20% of the spore's protein is degraded, providing the source of amino acids for biosynthesis of new protein and small molecules (such as nucleotides) during outgrowth (reviewed by Setlow, 1988). The spore's enzymes are not degraded. Rather, a group of small acid-soluble proteins (SASP) are the source of the amino acids. These unique proteins, located in the core and sensitive to proteolysis, conprise 8 to 20% of the protein in the spore. Their molecular weight is low (5–11 kDa) and although they are not histones, they bind to the spore DNA. The proteins are degraded by a unique protease that has an absolute specificity for these proteins. They are synthesized late in sporulation. Several of the five known SASP genes (referred to as *ssp*) have been cloned and in addition to coding proteins supplying amino acids in germination their products may have other roles. One has been shown to be involved in ultraviolet (UV) resistance.

Many germination mutants (abnormal germination phenotypes) have been described (reviewed by Moir et al., 1986; Foster and Johnstone, 1989). The *ger* (germination) genes are considered a subclass of *spo* (sporulation) loci, and are made up of several classes: I, structural genes for germination mechanism components; II, regulatory genes for class I; III, post-translation processing and assembly genes; and IV, genes for synthesizing spore structure (e.g., cortex) required for germination.

Outgrowth is the period during which the spore gradually becomes a vegetative cell and initiates new macromolecular synthesis. Genes associated with this period are *out* genes. DNA is replicated relatively late in outgrowth, just before division. The vegetative cell is then capable of undergoing various morphological and biochemical changes which lead either to a series of symmetric cell divisions if sufficient nutrients are present, whereas in stressful times (particularly nutrient limitation), subsequent spore formation or the production of a spore without intermittent cell division can occur. The latter is known as microcycle sporulation (Vinter and Slepecky, 1965).

Sporulation

Electron microscopical analyses of cells during sporulation has revealed seven stages (reviewed by Fitz-James and Young, 1969). The various stages are shown in Fig. 2. Vegetative cells are considered to be Stage 0. Upon induction input prior to actual sporulation, the nuclear material is in an axially disposed filament. This is stage I. However, since such a pattern does not appear to be unique to sporulating cells, current practice refers to cells in stages prior to stage II as pre-septation cells. Segregation of the chromatin material to the poles of the cell occurs concomitantly with the invagination of the plasma membrane in an asymmetrical position on the cell which fuses to complete the spore septum. This is stage II. The mode of formation of this septum is similar to the formation of the transverse septum of symmetric vegetative cell division. Indeed, it has been proposed that sporulation because of this and some other similarities is a modified prokaryotic division (Hitchins and Slepecky, 1969) and models for that view have been presented (Freese and Heinze, 1983). In sporulation, the division of the cell is not equal and subsequent proliferation of the larger cell's plasma membrane leads to complete engulfment of the "forespore" and liberation of the immature spore, surrounded now by a double unit membrane, into the cytoplasm of the larger cell. This completes stage III. This is a key step since this double membrane now has different trans-

port properties owing to the opposing polarity of the two membranes.

During sporulation the vegetative cell is divided into two compartments each having a different fate and each displaying different patterns of gene expression (reviewed by Setlow, 1989). At this time, the cell is "committed" to complete the process of sporulation. The small cell eventually becomes the core of the spore while the large cell, the mother cell, goes on to produce the outer protective layers of the spore and then lyses to release the spore. Cortex material similar to vegetative cell peptidoglycan (but differing in the degree of cross-linking and other aspects) is laid down between the unit membranes, and its deposition corresponds in time to the accumulation in the core of DPA and calcium. Stage IV is now completed. Studies with cortex-less mutants show that the cortex is needed for refractility of the spore (when the spores become refractile, they can be seen in the phase-contrast microscope) and for accumulation of DPA. The cortex plays a fundamental role in the dehydration of the spore (reviewed by Gould, 1983).

During Stage V, protein coats are synthesized by the mother cell. There are about 10 major coat proteins in *B. subtilis* and they are encoded by *cot* genes, seven of which are known (Losick et al., 1986). The coat proteins are placed around the outside of the forespore. In some species, an additional protein layer called an exosporium is synthesized. Since the coat may play important roles in protection of the spore and its subsequent germination, it has been the subject of many investigations (reviewed by Aronson and Fitz-James, 1976; Losick et al., 1986). Electron microscopy reveals that *B. cereus* contains an outer coat showing a cross-patched pattern, an inner pitted layer, and a thin layer, the undercoat, while other species show distinct differences. *B. subtilis* possesses a very thick multilayered coat with an outer striped layer and *B. thuringiensis* has a coat deficient in the outer cross-patched layer. Differences show up as well within the major structural polypeptides and coat-associated proteases. These differences may be responsible for the variation found in germination and certain resistant properties (other than heat and UV resistance) of various species.

During vegetative growth and subsequent sporulation, a variety of proteases are produced (reviewed by Priest, 1977). There are six extracellular proteases and at least three major intracellular proteases—ISP, esterase A, and esterase B. They may be involved with turnover of intracellular proteins, the processing of protein precursors for spore coats, or inactivation of later sporulation enzymes, as well as other functions. As with other aspects of *B. subtilis* physiology,
Fig. 3. Cross-section of *Bacillus megaterium* containing a spore and showing the sporangium (cell), cell protoplast (CP) and wall (CW), spore coat (SC), spore cortex (SCor), spore membrane (SM), and spore protoplast (SP). ×120,000. (Norris et al., 1981.)

there are other considerations. Even though the genes *apr*, *npr*, *epr*, and *isp*, which code for the proteases alkaline (subtilisin), neutral (metallo-) "new" serine, and major intracellular serine, respectively, can be deleted, there still is some protease activity (Sloma et al., 1988). This finding suggests that there are other unindentified proteases.

As the spore matures (stage VI), it becomes resistant to heat and to a variety of organic solvents. Final lytic enzymes lyse the sporangial or mother cell liberating the free spore (stage VII). Figure 3 shows a cross section of a mature and heat-resistant spore. If the free spore is placed among the proper nutrients it will germinate, completing the cycle. The sporulation process takes 6 to 8 h at 37°C in *B. subtilis*.

Many other biochemical and physiological events occur during sporulation in addition to those indicated in Fig. 2 and those that can be surmised to be linked with the morphologically identified stages. Some vegetative enzyme activities disappear, some remain, others are modified, and new sporulation specific enzymes are synthesized. The number of sporulation-associated events is uncertain, but the genetic evidence suggests as many as 200 genes in 40 to 50 operons are involved (Losick et al., 1986; Mandelstam and Errington, 1987; Piggot, 1989; Youngman et al., 1989). Currently the genetic map, which includes sporulation and germination genes as well as all-known vegetative cell genes, contains 700 loci, more than 300 of which have been cloned and 180 of those sequenced (reviewed by Piggott, 1989). The ordered appearance of cytological and biochemical changes

implies a sequential reading of the genome. The genetic data are consistent with there being a single linear dependent sequence to stage III with a more complex pattern of gene expression beyond that stage.

The genotype of mutants blocked at the various morphological stages in sporulation (as determined by electron microscopy) are designates *spoO*, *spoII*, *spoIII*, etc. For example, a *spoII* mutant would be arrested in stage II. Within each genotype, the designation *A*, *B*, *C*, etc. identifies different genetic locations; for example, *spoIIA*, *spoIIB* identify two separate mutations that cause arrest of developmental stage II. Eight loci have been shown to be concerned with stage 0, the five principal spoO genes being *spo0A*, *B*, *E*, *F*, and *H*. These *spo0* mutants have pleiotropic effects on the phenotype, suggesting that their gene products regulate the expression of several genes. They do not make polar septa (the asymmetric division) or Stage 0 associated products—proteases, antibiotics and transformation competent cells. There are suppressors of spo0 mutations, i.e., suppressor mutations can restore sporulation in some spo0 mutants to the wild type level. For example, *sof-I* can suppress defects in *spo0F*, *B*, and *E* (Hoch et al., 1985). Others include *arbA* and *arbB* suppressors of *spo0A* mutations; *rvtA*, a *spo0* repressor; *ssa*, a reliever of suppression of alcohols; *crs*, an alleviator of glucose repression of sporulation; and *sapA* and *sapB*. suppressors involved with alkaline phosphate induction (Losick et al., 1986). Studies on these extragenic suppressors have given insights into the role of *spo0* mutants.

Sporulation, normally repressed at high growth rates in the presence of excess nutrients, will ensue at the beginning of stationary phase (arbitrarily defined as t_0) in batch culture upon limitation of carbon, nitrogen, or phosphate (reviewed by Smith, 1989, and Sonenshein, 1989). The initiating signal for sporulation is not known. However, sporulation initiation is associated with a decrease in the intracellular GTP pool (reviewed by Freese and Heinze, 1983). Decoynine, a drug that artificially reduces GTP level, induces sporulation even in the presence of excess nutrients. There may be a connection between GTP levels and a proposed sensing mechanism as follows: *spo0A*, *B*, and *F* share significant homology and *A* and *F* products show partial homology with proteins such as OmpR, NtrC, and SfrA which are "sensing proteins" involved in the transduction of various environmental signals (Trach et al., 1985; Nixon et al., 1986). Thus, *spo0A* and *spo0F* may play a role in sensing starvation and transferring a signal to other genes (see review by Smith, 1989, on the initiation of sporulation). A gene for a protein

kinase that phosphorylates sporulation regulatory proteins Spo0A and Spo0F has been characterized (Pergo et al., 1989). The gene, *kinA*, previously known as *spo11J*, has been shown to code for a protein that is homologous to the transmitter class of proteins (Stragier, 1989). Defects in the methylation of a membrane-associated 40-kDa protein in some *B. subtilis* *spo0* mutants suggests that protein methylation also may be a part of the nutrient-sensing system (Golden and Bernlohr, 1989).

Multiple forms of RNA polymerase are of considerable importance in sporulation (reviewed by Doi and Wang, 1986; Losick et al., 1986; Losick and Kroos, 1989; Moran, 1989; Setlow, 1989; Stragier, 1989). The holoenzyme is made up of an enzyme core comprised of subunits beta, beta′ and alpha (the products of genes *rpoB*, *rpoC*, and *rpoA*, respectively) and attached sigma factors (the products of genes to be designated), regulatory proteins that determine the promoter specificity. Currently, there are nine known sigma factors, four associated with vegetative cells and five involved in sporulation (see Table 8). Losick and Pero (1981) suggested there is a succession of different sigma factors governing the transcription of the various temporal classes of sporulation genes.

The first acting sporulation sigma is ;gs;xH which is required for the initiation of sporulation and it is involved with the transcription of a later gene, *spoVG*.

A key point in sporulation is stage II, which is the result of the asymmetric division event. stage II mutants and the associated gene products or functions are as follows: *spoIIAA* σ^E processing); *IIAC* (σ^E factor); *IIE* (pro σ^E); *IIGA*σ^E processing protease); *IIGB* (p^{31}; σ^E); *IIN* (Fts homology) and *IIJ* (ntrB protein kinase) (Leighton cited in Stragier (1989), and Stragier (1989)). That the *spoIIN* product has homology with *E. coli* Fts, a protein involved in symmetrical cell division, may suggest that the level of Fts controls the asymmetric division. In turn, the functions of the other *spoII* mutations listed above implies a rather complicated mechanism for the synthesis of σ^E. The sporulation septum (stage II), dependent on *spoIIAC* (σ^F) and *spoIIE* products, is required for *spoIIGA* processing activity, i.e., conversion of pro-σ^E by proteolytic cleavage to σ^E. The important finding by Stragier (1989) of the coupling of gene expression to morphogenesis may be a recurrent theme throughout other aspects of sporulation.

After Stage II, compartmentalization of sigma factors occurs. σ^E is active both in the mother cell and forespore compartment. σ^G acts only in the forespore compartment (Setlow, 1989) while σ^K, the product of *sig K*, a composite gene from *IVCB* plus *IIC* (due to a chromosome

Table 8. *Bacillus subtilis* sigma factors.

Modified from Helmann and Chamberlain (1988); Moran (1989); and Stragier (1989).

rearrangement requiring *SpoIIID* and a recombinase) acts only in the mother cell (Losick and Kroos, 1989). σ^K directs the transcription of *cotA* and *cotD*, spore coat genes.

This brief overview of some of the emerging information on regulation of gene expression during sporulation reflects the current view of a network of dependent pathways in which activation of developmental genes depends on the products of other developmental genes (Losick and Kroos, 1989).

Surface Structures of *Bacillus*

S-Layers

Crystalline surface layers of protein or glycoprotein subunits, called S-layers, are found in members of the genus *Bacillus* (reviewed by Sleytr and Messner, 1988). S-layers of individual strains of *Bacillus* have been shown to differ in molecular weight (40–200 kDa), the degree of glycosylation of the subunits, and the geometry of the S-layer lattice. For example, *B. stearothermophilus* contains one S-layer consisting of two types of glycan chains, one being a unique type of protein-carbohydrate linkage. On the other hand, *B. brevis* contains two S-layers, termed the outer wall protein (OWP) and the middle wall protein (MWP), external to the peptidoglycan layer. These form a hexagonal array in the cell wall. The nucleotide sequence of the entire MWP-OWP gene operon is known (Tsuboi et al., 1988). The gene encoding an S-layer protein of *B. sphaericus* has been cloned and sequenced (Bowditch et al., 1989). Not all *Bacillus* species contain S-layers and some strains within a species may lack such a layer. Furthermore, the type of lattice may vary from species to species and within strains of a species. *B. alvei*, *B. anthracis*, and *B. brevis* show a hexagonal array; *B. cereus*, *B. fastidiosus*, "*B. macroides*," *B. megaterium*, *B. psychrophilus*, and *B. schlegelii* present a square lattice, while strains of *B. stearothermophilus* can be obtained that individually have one of the three types (Claus and Berkeley, 1986).

As with S-layers of other bacteria, their function in *Bacillus* is unknown. However, since it has been demonstrated that the S-layer can physically mask the negatively charged peptidoglycan sacculus in *B. stearothermophilus* and prevent autoagglutination, it has been postulated that the layer may play a key role in bacteria-metal interactions (Sleytr and Messner, 1988).

Capsules

The capsule (a homopolypeptide of D-glutamic acid) of *B. anthracis* as a virulence factor has been studied extensively (see The Genus *Bacillus*—Medical in this Volume). Other bacilli, such as *B. subtilis*, *B. megaterium*, and *B. licheniformis*, possess capsules containing the homopolypeptide of D- or L-glutamic acid as well (Makino et al., 1989). Some *Bacillus* species, e.g., *B. circulans*, *B. mycoides*, and *B. pumilus*, produce carbohydrate capsules. For example, *B. circulans* forms an extracellular polymer consisting of glucose and glucuronic acid (Claus and Berkeley, 1986). In the case of *B. megaterium* a heteropolysaccharide composed of D-glucose, D-xylose, D-galactose, and L-arabinose has been found in one strain (Cassity and Kolodziej, 1984).

Flagella

Most *Bacillus* species possess peritrichous flagella. Although some use has been made of H-antigens in setting up serotyping schemes, they have not been widely adopted (Claus and Berkeley, 1986). Chemotaxis has been studied extensively in *B. subtilis* (Ordal and Nettleton, 1985).

Cell Walls

Almost all *Bacillus* species tested have vegetative cell walls made up of peptidoglycan containing *meso*-diaminopimelic acid (*m*-DAP). The exceptions (*B. sphaericus* and the related species, *B. pasteurii* and *B. globisporus*) contain lysine instead (Bartlett and White, 1985). But even those species, as all others, contain *m*-DAP in the peptidoglycan of their spore cortex. Cell wall turnover in Gram-positive bacteria, particularly *Bacillus* species which have been useful models, has been reviewed by Doyle et al. (1988). In addition to peptidoglycan in the cell wall, all *Bacillus* species contain large amounts of an anionic polymer, such as teichoic acid (a glycerol or ribitol-based polymer joined together by phosphodiester linkages to form a flexible linear strand) or teichuronic acid (uronic acid-based polymer) which are bonded to muramic acid residues. The type of this anionic polymer present depends on the levels of phosphate and magnesium in the growth medium. The glycerol teichoic acids vary a great deal between *Bacillus* species and within species. For example, *B. subtilis* can contain either glucosyl α or β (1→2) glycerol or glucosyl α (1→6) galactosyl α (1→1 or 3) glycerol), while *B. licheniformis* contains galactosyl α (1→2) glycerol. However, they are joined to the peptidoglycan through a common linkage disaccharide, acetylmannosaminyl(1→4)*N*-acetylglucosamine (Kaya et al., 1984).

As in other Gram-positive bacteria, lipoteichoic acids are found associated with most of the cell membranes of *Bacillus* species. These compounds are involved in the synthesis of wall

teichoic acids as regulators of autolytic activity and as scavengers of bivalent ions. Those so tested in *Bacillus* fall into three groups based on the presence or absence of *N*-acetylglucosamine branches in the backbone chains of their lipoteichoic acids—hydrophilic poly (glycerol-phosphate) chains and hydrophobic gentiobio-syldiacylglycerol anchors (Iwasaki et al., 1989). Group A is made up of strains of *B. subtilis*, *B. licheniformis*, and *B. pumilus*; group B, other *B. subtilis* strains and *B. cereus*, and group C, *B. polymyxa* and *B. circulans*.

Macrofibers

Macrofibers are multicellular and multistranded structures, hundreds of micrometers in length, produced by autocatalytic mutants of *B. subtilis* (Mendelson, 1978). These left- or right-handed helical structures have been used to study cell wall structure and growth. They are thought to reveal cell-surface molecular organization and force interactions in the cell wall not readily elucidated in the wild type, single-celled organism. The establishment and maintenance of macrofiber structure is influenced by both genetic and physiological factors (Briehl and Mendelson, 1987; Surana et al., 1988).

Membranes

The membranes of *Bacillus* species have been studied extensively because of their intrinsic interest; as a model of membrane structure in Gram-positive cells; with regard to their role in sporulation and germination; with respect to explanations for thermophily; and other reasons. For example, one explanation for the ability of thermophilic microorganisms such as *B. stearo-thermophilus* to grow at high temperatures is that the physical properties of the membrane are changed due to changes in the lipid composition in response to growth temperature (Gould, 1983).

There is great diversity in the range and type of lipids in *Bacillus* membranes (see review by Minnikin and Goodfellow, 1981) and wide variation in the fatty acids are found. The main phospholipids present are phosphatidylglycerol, diphosphatidylglycerol, and phosphatidyletha-nolamine; however, others are found as well. The major isoprenoid quinones are menaquinone, and most species contain menaquinones with seven isoprenoid units (MK-*7*). *B. acidocaldarius* is the exception and possesses MK-*9* (Minniken and Goodfellow, 1981).

Two-dimensional polyacrylamide gel electrophoresis (PAGE) has been used to attempt to resolve all *B. subtilis* membrane polypeptides (see Shohayer and Chapra [1985] for one such study). Several membrane enzymes have been isolated and characterized, such as the lactate, malate, glycerate-3-phosphate, NADH, and succinate dehydrogenases.

Because of interest in synthesis and modification of the peptidoglycan layer, much attention has been paid to penicillin-binding proteins. Six have been found in *B. subtilis*, but one of the most penicillin-sensitive binding proteins, number 4, has been found to be absent from *B. subtilis* 168 (Buchanan, 1987).

Genetic Studies

The discovery of transformation in *B. subtilis* strain 168 by Spizizen (1958) was largely responsible for focusing attention on the genetics of the genus *Bacillus*. Strain 168 is thought to be a derivative of the type strain *B. subtilis* Marburg (see Hemphill and Whiteley, 1975), and is one of a relatively few bacilli in which competence for DNA uptake has been found to occur as a natural part of the life cycle. As a consequence of Spizizen's discovery and the later isolation of generalized transducing phages, our knowledge of the chromosomal organization of *B. subtilis* is second only to that of the enteric bacteria. (About one-half as many genetic markers are known in *B. subtilis* as in *Escherichia coli*.) Furthermore, the identification of numerous genes affecting sporulation in *B. subtilis* is providing a means for analyzing this complex developmental program, which is largely unique to the Gram-positives.

Transformation

The establishment of a competent state in broth culture is most efficiently brought about in a minimal salts medium (Anagnostopoulos and Spizizen, 1961; Bott and Wilson, 1967). As the bacteria enter stationary phase in this medium, a maximum of 20% become competent, with a 1 to 2% transformation frequency for a given marker. The development of competence is associated with a reduction in macromolecular synthesis that is initiated well before cells are transformable. Competent bacilli are relatively metabolically latent, and have a lower buoyant density compared to noncompetent bacteria (Dooley et al., 1971; Hadden and Nester, 1968). Although the period of competence overlaps the time in which sporulation is initiated, the two forms of physiological differentiation are thought not to be connected. Different media are preferred for the two processes and commitment to competence is reversible. Several lines of research suggest that

the establishment of competence is coincidental with, and perhaps induces, a DNA-repair system analogous to the SOS regulon in *E. coli* (Love et al., 1985).

The development of the capacity of *B. subtilis* to take up DNA is associated with the appearance of several novel cellular proteins. Among these is a 75-kDa protein complex which has been isolated from the membrane of competent cells (Smith et al., 1985). The complex consists of two subunits of 18 kDa (polypeptide A) and 17 kDa (polypeptide B). Mutants lacking subunit A do not bind DNA to the cell surface whereas those deficient in B are defective in DNA entry. The 75-kDa protein complex also has nuclease activity that is probably associated with polypeptide B. A nuclease is expected, because it is known that one strand of transforming DNA is hydrolyzed in the process of entering the cell, resulting in a single-stranded product on the cytoplasmic side of the membrane (Davidoff-Abelson and Dubnau, 1973a, 1973b). Competence factors that interact with the membrane have also been reported in *B. stearothermophilus* (Streips and Welker, 1971). *B. subtilis* cells show little specificity with regard to DNA uptake and may be transformed with homologous chromosomal DNA, plasmid DNA, or transfected with bacteriophage DNA.

There is evidence that strands of transforming DNA enter the cell at sites on the membrane where the chromosomal DNA is attached (teRiele et al., 1984). The penetrating DNA, now reduced to a single-strand form, is then brought in contact with the homologous region of the recipient chromosome. This step is probably mediated by the 45-kDa protein product of the *B. subtilis recE* gene and results in a complex in which the transforming DNA begins to displace one strand of the chromosomal DNA while hydrogen-bonding to the complementary strand. A continuation of the displacement reaction allows pairing and integration of several thousand bases of transforming DNA into the chromosome, while an equivalent amount of the homologous strand is removed and degraded.

Considerable thought has been given to the question of whether transformation is associated with genetic exchange in natural populations of bacilli (see Stewart and Carlson, 1986, for a review). The complexity of the transformation process with its requirement for unique competence factors appearing only at stationary phase suggests that the capacity to take-up exogenous DNA offers some selective advantage in the evolution of these bacteria. The fact that competence occurs only late in the growth cycle probably means the system is not designed to obtain DNA as a nutrient. Ephrati-Elizur 1968 found that *B. subtilis* cells excrete high-molecular-weight DNA into liquid culture as they grow. Under natural conditions this could be the source of donor DNA. Graham and Istock (1978) demonstrated that genetic exchange, thought to be mediated by transformation, occurs at high frequency between genetically labeled strains of *B. subtilis* in soil. Also, transformation frequencies in cultures in which the bacteria are allowed to attach to sand grains are much higher than in the standard liquid culture procedure (Lorenz et al., 1988).

Generalized Transduction

Bacteriophage capable of mediating generalized transduction have been reported in many species of *Bacillus* including *B. subtilis*, *B. cereus*, *B. megaterium*, *B. thuringiensis*, *B. anthracis*, and *B. stearothermophilus*. Thus, transduction offers an immediate advantage for genetic analysis over transformation in that it is applicable to more strains of these bacteria. In addition, some phages transduce fragments of DNA much larger than can be transferred via transformation, and this facilitates linking distant markers. PBS1, a bacteriophage that infects *B. subtilis* 168, can incorporate 5 to 10% of the bacterial chromosome in a single virion particle, and was instrumental in constructing the complete circular chromosomal map of *B. subtilis* (Lepesant-Kejzlarova et al., 1975). On the other hand, small DNA molecules such as those of some plasmids are not efficiently packaged in large phages, but can be transduced by a variety of small bacteriophages (Canosi et al., 1982). Some generalized transducing phages have relatively broad host ranges and can transfer plasmids between different species of bacilli (Ruhfel et al., 1984).

Little is known about the mechanism by which transducing particles are formed. PBS1 appears to package bacterial DNA randomly. There is little evidence for packaging sites as are indicated in *Salmonella* phage P22 (Jackson et al., 1978; Schmieger, 1982, 1984). A *pac* site has been located in the genome of the small generalized transducing phage SPP1. However, its relevance, if any, to packaging transducing DNA is not clear (Deichelbohrer et al., 1982, 1985).

The process by which transducing DNA becomes incorporated into the recipient bacterial chromosome differs from that discussed earlier for transformation. In transduction, the donor DNA is thought to enter the infected cell as double-stranded DNA which then synapses with the homologous region of the recipient chromosome. Incorporation of the transducing fragment presumably results from a double

crossover between the two DNA molecules. In support of this model, mutants of *B. subtilis* deficient in recombination functions have a reduced capacity to be transduced, while they can be transformed (Dodson and Hadden, 1980).

Other important *Bacillus* generalized transducing phages include CP15, a phage originally shown to transduce *B. cereus* (Thorne, 1968) but which can transfer plasmids between *B. cereus*, *B. thuringiensis*, and *B. anthracis* (Ruhfel et al., 1984). Bacteriophage MP13 has been important in mapping the chromosome of *B. megaterium* (Vary et al., 1982), and TP-13 and TP18 have been similarly used in genetic studies of *B. thuringiensis* (Barsomian et al., 1984).

Specialized Transduction

Specialized transduction has been reported in several *B. subtilis* phages including π105 (Shapiro et al., 1974), SPβ (Zahler et al., 1977), and π3T (Odebralski and Zahler, 1982) and *B. amyloliquefaciens* phage H2 (Zahler et al., 1987). The most carefully examined of these is SPβ, a temperate bacteriophage that is normally carried as a prophage in *B. subtilis* 168 (Warner et al., 1977). SPβ can transduce markers proximal to its normal attachment site *attB* SPβ between the markers *ilvA* (threonine dehydratase) and *kauA* (ketoacid uptake) located near the terminus of chromosomal replication. In addition, SPβ prophage will insert at a variety of aberrant positions when it lysogenizes mutants of *B. subtilis* lacking *attB* SPβ. Induction of these lysogens gives rise to specialized transducing phages carrying genetic markers near the novel sites of integration (see Zahler, 1982, for a review). The gene order of SPβ prophage is a circular permutation of that present in the phage DNA (Spancake et al., 1984). Specialized transducing particles are thought to originate from errors in excision when the prophage is induced. The crossing-over event that leads to reformation of a circular phage DNA during induction may be displaced, resulting in removal of a portion of the bacterial DNA contiguous to the right or left boundaries of the prophage. Encapsidation of such hybrid DNA produces a specialized transducing particle.

Two types of transductants are recognized in the SPβ system (Zahler, 1982). The bacterial portion of the transducing phage DNA may undergo recombination with and replace the homologous region of the genome of the recipient. This so-called "replacement transduction" is similar to generalized transduction, except that only a limited number of genetic markers are involved. On the other hand, the infecting phage-bacterial DNA may incorporate as a prophage to produce a bacterium diploid for the *B. subtilis* genes associated with the prophage. Such "addition transductions" are most likely to occur if the recipient bacterium is already lysogenic for SPβ. The resulting merozygote may be used in complementation studies if different alleles are present on the prophage and bacterial chromosomes.

Conjugative Plasmids

Fertility plasmids capable of bringing about their own transfer from one bacterium to another have been described in several species of *Bacillus*. The capacity to produce the insecticidal delta toxin crystal protein in *B. thuringiensis* is encoded in large plasmids. Gonzalez et al. (1982) found that three strains of this bacterium transmitted the crystal-protein phenotype to *B. thuringiensis* variants which had lost the plasmid. Moreover, these plasmids could also be transferred to *B. cereus* and yielded transcipients that produce crystal protein. Battisti et al. (1985) reported the transfer of plasmids pXO11 and pXO12 from *B. thuringiensis* to *B. anthracis* and *B. cereus*. The transcipients, in turn, became effective donors, and in the case of those inheriting pXO12, also acquired the ability to produce parasporal crystals. Strains of *B. anthracis* that acquire plasmid pXO12 can subsequently mobilize and transfer nonconjugative plasmids present in the same cell. Using this system, the tetracycline resistance plasmid pBC16, the *B. anthracis* toxin plasmid pXO1, and the capsule plasmid pXO2 have been transmitted to *B. anthracis* and *B. cereus* recipients lacking these plasmids (Green et al., 1989). The small plasmid pBC16 is transferred at high frequency without direct interaction with pXO12; such transfer of a nonconjunctive plasmid is called donation. The large *B. anthracis* plasmids are apparently transferred by conduction. The latter involves formation of cointegrative molecules in the donor, and resolution of the cointegrates into pXO12 and the respective *B. anthracis* plasmid in the recipient. Cell-to-cell contact is necessary for plasmid transfer and is resistant to DNase, but little is known about the mechanisms or conjugative structures that may be involved.

A strain of *B. subtilis* (natto) has been found which carries a 55-kb self-transmissible plasmid (pLS20), which can be transferred to closely related strains and to restriction-deficient strains of *B. subtilis* (Koehler and Thorne, 1987). This plasmid also promotes the transfer of the tetracycline-resistance plasmid pBC16 from *B. subtilis* (natto) to a wide variety of *Bacillus* species including *B. anthracis*, *B. megaterium*, and *B. subtilis*. This is a much broader range of conjugative transmission than has been observed with the *B. thuringiensis* plamid. However, none of

the conjugative plasmids have been found to mobilize and transfer chromosomal markers as is observed with the F plasmid of *E. coli*.

In addition to the naturally occurring transmissible plasmids of *Bacillus*, Christie et al. (1987) have identified a conjugative transposon (Tn925) which transfers from *Streptococcus faecalis* to *B. subtilis*.

Bacteriophages

Bacteriophages that infect *Bacillus* are common in soil. In addition, many strains of this genus are naturally lysogenic for one or more prophages. The most extensively studied *Bacillus* phages are those associated with *B. subtilis*, and these have been reviewed by Hemphill and Whiteley (1975), Rutberg (1982), and Zahler (1988).

With some exceptions, *Bacillus* phages have relatively narrow host ranges, probably at least in part because of restriction systems that make phage grown in one host incompatible with another strain (Ando et al., 1982). With the exception of the phages of *B. subtilis*, no scheme of classification has been adopted to organize the phages of this genus. Therefore, the bacteriophages described here will be grouped according to life cycle.

Temperate Bacteriophages

Most strains of bacilli that have been carefully examined have been found to release phage particles. These are of two types: defective phages that can kill but do not productively infect other strains (see "Defective Bacteriophages," this chapter), and those that grow on and lysogenize new host bacteria. *B. subtilis* 168 is lysogenic for phage SPβ and also releases defective phage PBSX. As an extreme, *B. thuringiensis* subsp. *aizawai* is polylysogenic for five unique temperate phages (Reynolds et al., 1988). Temperate phages are easily obtained from nature. If samples of soil are placed in broth and the mixture heated 10 min at 80°C, most free phage and non-sporeforming bacteria are destroyed. When the culture is allowed to incubate several hours and

subsequently treated with mitomycin C, temperate phages are induced and released into the medium. (Some investigators inoculate the broth with the *Bacillus* strain of interest to enrich for phage, and then add mitomycin C.) The phages may then be recovered by filtering the solution and plating on an appropriate indicator.

Dean et al. 1978 have divided the temperate phages of *B. subtilis* and closely related species into four groups based upon serology, immunity, and physical characteristics (Table 9); the defective phages may be considered a fifth class. Several group III phages including *B. subtilis* phages SPβ and π3T and *B. amyloliquefaciens* phage H2 can mediate specialized transduction. Group I phage π105 also transduces genes close to its prophage attachment site (Shapiro et al., 1974). In addition, π105, SPβ, ρ11, and others have been used as cloning vehicles, mostly for *B. subtilis* genes (see Zahler, 1988, for a review).

Temperate bacteriophages often alter the biochemistry or phenotype of lysogenic bacteria and several examples of such prophage conversion have been observed in *B. subtilis*. Strains of this bacterium lysogenic for SPβ release a bacteriocin-like substance called betacin (Hemphill et al., 1980) which kills some *Bacillus* strains that do not harbor the SPβ prophage. Most group III bacteriophages including π3T, ρ11 and Z (but not SPβ) contain the structural gene for thymidylate synthetase, and express this gene continuously in lysogens. Stains of *B. subtilis* lysogenic for SP02 cannot be productively infected with virulent phage π1 (Rettenmier and Hemphill, 1974), and bacilli lysogenic for SPβ are protected by a similar interference system active against π1*m* (Rettenmeir et al., 1979).

Defective Bacteriophages

Many species of *Bacillus* including *B. subtilis*, *B. amyloliquefaciens*, *B. pumilis*, and *B. laterosporus* release defective phages whose presence is revealed by their bactericidal activity against other strains or species of this genus (Hemphill and Whiteley, 1975; Steensma et al., 1978; Zahler, 1988.) For example, *B. subtilis* strain 168 releases a defective phage called

Table 9. Major groups of temperate *B. subtilis* phages.

Group	Example	DNA size (kb)	Virion dimensions (nm)		Other members of group
			Head	Tail	
I	φ105	40	52 × 52	10 × 220	ρ14
II	SPO2	40	50 × 50	10 × 180	—
III	SPβ	126	72 × 82	12 × 358	φ3T, ρ11, Z, SPR
IV	SP6	53	61 × 61	12 × 192	—
V	PBSX	13	45 × 45	20 × 200	PBSZ

Modified from Dean et al. (1978) and Zahler (1988).

PBSX, which kills the cells of *B. subtilis* strain W23. Electron microscopic examination of the culture supernatant of strain 168 reveals typical phage particles. However, the PBSX virions cannot replicate and produce plaques; rather, they act much like a bacteriocin. *B. subtilis* strain W23, in turn, releases defective phage PBSZ, which has a bacteriocin activity against strain 168.

Despite being defective, these phages act much like other temperature viruses. Although small numbers are typically present in the culture supernatant, lysogens may be induced with UV light or mitomycin C and lyse and release large numbers of particles. (The situation is often confusing, however, because many bacilli including *B. subtilis* 168 are simultaneously lysogenic for one or more nondefective temperate phages.) Virions of PBSX are unmistakably phage-like in structure. They have a rather small head (45 nm in diameter) and a cylindrical, contractile tail 18 by 200 nm. The genes for structural proteins of PBSX have been mapped to a chromosomal position between the markers *metA* and *metC* (Thurm and Garro, 1975). PBSX and presumably other phages of this group are defective for more than one reason. First, the particles do not contain an identifiable phage DNA. Instead, PBSX packages randomly selected 13-kb fragments of bacterial chromosomal DNA (Anderson and Bott, 1985). Second, although PBSX virions attach efficiently to susceptible strains and the tail appears to contract, the DNA in the phage heads is not injected (Okamoto et al., 1968).

Lytic Bacteriophages

Lytic bacteriophages that infect *Bacillus* are also common in soil and water. Again, the most detailed studies are of phages that infect *B. subtilis* or closely related species (see Hemphill and Whiteley, 1975, for a review.) Although many of these viruses are intrinsically interesting, two groups of subtilis phages have been the focus of studies on the regulation of viral transcription (see Geiduschek and Ito, 1982). The first class, which includes SP01 and SP82, is distinguished by the replacement of thymine by hydroxymethyluracil (hmU) in the viral DNA. The second class includes $\pi 29$ and relatives, which are very small, linear double-stranded DNA phages.

SP01 and SP82 have very complex temporal programs of transcription involving at least three phases of gene expression designated early, middle, and late. Early gene expression starts within 1 min of infection, and is thought to use the host RNA polymerase. Middle genes are activated about 4 min after infection, and the expression of late genes (which are turned on asynchro-

nously) is first detected 10 min into the latent period. Initiation of transcription of the middle and late genes involves structural modifications of the *B. subtilis* RNA polymerase, such that the enzyme can recognize unique middle and late phage promoters that are not used by the unmodified polymerase (Tarkington and Pero, 1979). The product of at least one SP01/SP82 gene is thought to associate with the enzyme to activate middle genes (Hyde et al., 1986), and at least two other phage-encoded polypeptides appear to modify the polymerase to synthesize late mRNAs (Fox, 1976; Tjian and Pero, 1976). Other viral genes associated with late transcription have been identified, but these may be required to initiate DNA replication, which is also involved in transcriptional control. Even as new mRNAs are made, transcription of at least some early and middle genes is repressed at characteristic times in the latent period of SP82 and SP01. Proteins that bind to phage DNA and block RNA synthesis have been isolated from infected cells, but the actual mechanism of repression is not clear. Although not directly related, the study of gene expression in these subtilis phages has influenced the investigation of somewhat analogous changes in RNA polymerase structure associated with sporulation.

Transcription of the $\pi 29$ genome also involves early and late mRNAs, which in this case are transcribed from different strands of the viral DNA. Early RNA is transcribed from the light (L) and late RNA from the heavy (H) strand. In vitro, *B. subtilis* RNA polymerase synthesizes early mRNA from as many as eight promoters (Mellado et al., 1988). At least a portion of the host RNA polymerase is also used for synthesis of late RNA, which is apparently initiated from a single promoter called A3. The latter has a −35 region that differs somewhat from the consensus −35 region of *B. subtilis* promoters (Vlcek and Paces, 1986). Transcription from A3 requires protein P4 encoded by $\pi 29$ gene 4 (Mellado et al., 1988).

Pseudotemperate Phages

Pseudotemperate bacteriophages are lytic phages that establish a relatively long-term association with bacteria that mimics true lysogeny (see Hemphill and Whiteley, 1975). Following adsorption and penetration, further advancement of the viral development cycle is often delayed; some infected cells continue to grow, divide, and even sporulate. A portion of the daughter cells may even be cured, and about one-half the spores produced from such cultures do not contain viral DNA. Pseudotemperate bacteriophages characteristically produce turbid plaques, and "pseudolysogens" obtained from

these plaques may be subcultured. The pseudolysogens apparently consist of a balance between infected cells in a delayed latent period, bacteria containing maturing phage, and uninfected bacilli.

Included among the pseudotemperate phages are several of the best-known transducing phages of *Bacillus* such as *B. subtilis* phages PBS1, SP10, and SP15 and *B. thuringiensis* phage TP-13. The genomes of these viruses often contain modified DNA. For instance, the chromosome of PBS1 has a complete replacement of thymine by uracil (Takahashi and Marmur, 1963) and SP15 DNA substitutes 5-(4′-5′-dihydroxylpentyl)-uracil for thymine (Brandon et al., 1972).

Phage PBS1 (also referred to as PBS2, a clear-plaque mutant) and phage PMB12 carry out their entire development cycle in the presence of rifampin, an antibiotic that inhibits RNA synthesis by interacting with the bacterial RNA polymerase (Rima and Takahashi, 1974; Bramucci et al., 1977). In the case of PBS1 (PBS2), the resistance to rifampin is explained in part by the synthesis of a new phage-induced RNA polymerase that transcribes the viral late functions (Clark et al., 1974). Genetic evidence suggests that early RNA synthesis in PBS1 may be resistant to the drug because the virus, perhaps using a virion protein, induces a modification in the bacterial RNA polymerase that converts the latter to a resistant form (Osburne and Sonenshein, 1980).

One of the most intriguing phenomena associated with bacteriophage PMB12 is its capacity to convert pseudolysogens of certain sporulation-negative (*spo*) mutants of *B. subtilis* to a Spo+ phenotype (Kinney and Bramucci, 1981). Conversion has been observed in several stage O mutants, as well as in *B. subtilis* variants deficient in sporulation due to changes

in bacterial RNA polymerase or 30S ribosomes. At least three PMB12 genes are involved in spore conversion. The products of these genes apparently interact with host-cell pathways at the earliest stages of sporulation. Conversion of spore-negative mutants has also been observed with *B. pumilis* phage PMB1 (Bramucci et al., 1977) and numerous other phages which infect this species (Keggins et al., 1978). Bacteriophage TP-13 similarly converts oligosporogenic, acrystalliferous mutants of *B. thuringiensis* to spore-positive, crystal-positive phenotype (Perlak et al., 1979). This phage also mediates generalized transduction of large DNA fragments.

Plasmids

Plasmids are of widespread occurrence in the genus *Bacillus* and have been found in most species that have been screened. The vast majority are cryptic plasmids, that is, their presence has not been correlated with any unique property of the bacterial host. Although efforts have been made to analyze the relationship between different plasmids in a few species by comparing DNA-restriction fragment profiles, there is no accepted scheme for systematically classifying plasmids within the bacilli. Further confusing the study of plasmids in *Bacillus* is the fact that some of those used as vectors for gene cloning, such as pUB110, were actually derived from *Staphylococcus aureus* (Gryczan et al., 1978).

As shown in Table 10, some of the *Bacillus* plasmids do confer a recognizable phenotype to cells which carry them, such as antibiotic resistance, synthesis of toxins, unique metabolic activities, and transconjugation. Because of the medical and economic importance of their hosts, the plasmids conferring virulence in *B. anthracis*

Table 10. *Bacillus* plasmids.

Bacterium	Plasmid	DNA size (kb)	Phenotype associated with plasmid	Reference
B. anthracis	pXO1	168	Exotoxin (lethal factor, edema factor, protective antigen)	Mikesell et al., 1983 Tippetts and Robertson, 1988
	pXO2	85.6	Capsule	Green et al., 1985
B. cereus	pBC7	69	Bacteriocin	Bernhand et al., 1978
	pBC16	4.3	Tetracycline resistance	Bernhand et al., 1978
B. pumilus	pBL10	6.8	Bacteriocin	Lovett et al., 1976
B. subtilis	pIM13	2.2	Erythromycin resistance	Mahler and Halvorson, 1980
B. subtilis (natto)	pLS19	5.4	Polyglutamate production	Hara et al., 1982
	pLS20	55	Self-transmissible plasmid, which also promotes transfer of other plasmids	Koehler and Thorne, 1987
B. thuringiensis	pXO12	112.5	Production of insecticidal crystal protein, and is a self-transmissible plasmid, which can co-transfer unrelated plasmids	Green et al., 1989
Bacillus species (thermophilic)	pTB19	26	Kanomycin and tetracycline resistance	Imanaka et al., 1981
	pTB20	4.3	Tetracycline resistance	Imanaka et al., 1981

and *B. thuringiensis* have been of increasing interest. Virulence in *B. anthracis* requires the production of a capsule composed of poly-D-glutamic acid and an exotoxin consisting of three components: protective antigen, lethal factor, and edema factor. The capacity to produce the capsule is associated with plasmid pXO2 (Green et al., 1985), and the constituents of the toxin are encoded in plasmid pXO1 (Mikesell et al., 1983). Strains losing either plasmid are rendered avirulent. With the help of fertility plasmid pXO12 derived from *B. thuringiensis*, both pXO1 and pXO2 have been transferred to bacilli lacking these plasmids (Green et al., 1989). In the case of pXO1, cured strains of *B. anthracis* have been restored to toxin production (Thorne, 1985). The association of the toxin with plasmids is of historical interest. The original Pasteur vaccine strains of *B. anthracis* were produced by subculturing this bacterium at high temperatures which are now known to inhibit replication of pXO1. Indeed, two existing Pasteur strains lack this plasmid (Mikesell and Vodkin, 1985).

The genes for delta-exotoxin crystal proteins of *B. thuringiensis* strains are carried in large plasmids (see The Genus *Bacillus*—Insect Pathogens in this Volume). These plasmids are somewhat divergent in size and the crystal proteins produced by *B. thuringiensis* strains differ in serology and toxicity to various insects (Höfte and Whiteley, 1989). Moreover, several of these plasmids, such as pXO12 of *B. thuringiensis* subsp. *thuringiensis* 4042, (Reddy et al., 1987; Green et al., 1989) have been shown to mediate conjugal transfer of themselves and other plasmids (see "Genetic Studies" this chapter).

The production of the parasporal body containing the crystal protein toxin is coordinated with sporulation; crystal protein gene expression begins about stage II (see Whiteley and Schnepf, 1986, for a review). Changes in transcription during sporulation are associated with modifications of RNA polymerase which enable the enzyme to recognize sporulation-specific promoters (see "Sporulation", this chapter). It has been suggested the activation of the crystal protein genes is also regulated by polymerase changes. DNA sequence analysis of the 133-kDa crystal protein gene from *B. thuringiensis* subsp. *kurstaki* HD-1-Dipel revealed two overlapping promoters, one used early in sporulation (BtI) and the other (BtII) activated midway through development (Wong et al., 1983). Comparison of these promoters with those of the carefully studied *B. subtilis* system show little sequence consensus with promoters that bind vegetative RNA polymerase. Brown and Whiteley (1988) have isolated an RNA polymerase from strain HD-1-Dipel that directs transcription in vitro from the BtI promoter and also transcribes crystal protein

genes from two other strains of *B. thuringiensis*. This polymerase contains a unique 35-kDa sigma subunit that is different from the major sigma subunit present in vegetative cells of *B. thuringiensis*. In addition, the presence of two regions of hyphenated dyad symmetry near the BtI and BtII promoters suggests that binding of other regulatory proteins in this region could be associated with gene expression.

Transcriptional Regulation in Biosynthetic and Catabolic Pathways

Bacillus species demonstrate great catabolic and biosynthetic versatility. It is only recently, however, that significant progress has been made in understanding how synthesis of enzymes is regulated. Again, most studies have concentrated on *B. subtilis* and closely related species.

Control of Biosynthetic Gene Expression

B. subtilis can be grown in minimal salts media with glucose as carbon source. Thus, this bacterium must have the capacity to synthesize de novo all amino acids, nucleotides, etc. As in the enteric bacteria, the structural genes for enzymes of common biosynthetic pathways are clustered on the *B. subtilis* chromosome (see Zalkin and Ebbole, 1988, for a review.) Such operon-like organization has been observed for the genes of the tryptophan, arginine, and isoleucine-valine-leucine synthesis. In addition, the sequences encoding the enzymes for purine (*pur* genes) and pyrimidine (*pyr* genes) occur in multicistron clusters in *B. subtilis* (Ebbole and Zalkin, 1987; Lerner et al., 1987), which is not the case in *E. coli*. Gene clustering is associated with coordinate control of gene expression at the level of transcription by the products of the pathways. The *trp*, *arg*, and *ilv* operons are repressed, respectively, by tryptophan, arginine, and leucine. The *pur* genes are repressed by adenine and guanine nucleotides and *pyr* by pyrimidines.

It does not appear that regulation of the biosynthetic operons is mediated primarily through repressors, although the *arg* pathway may be an exception (Smith et al., 1986). Rather, the favored means of control appears to be termination/antitermination (attenuation) mechanisms which affect the elongation of nascent mRNA molecules. In several operons studied, the 5′-end of the mRNA contains a leader of 100 to 300 nucleotides which does not encode part of the first structural gene. Within this leader is a region that can fold into two mutually exclusive secondary structures, one of which is a procaryote transcription termination signal. The other con-

figuration is an antiterminator stem-and-loop (hairpin) which allows full-length message to be made. Control then resides in changing the ratio of termination vs. antitermination secondary structure.

In enteric bacteria, the leader sequence of amino acid biosynthetic gene clusters includes an open reading frame (ORF) for a short peptide, which is generally enriched in codons for the amino acid synthesized by that pathway. The formation of termination vs. antitermination hairpins is modulated by the rate at which the leader polypeptide is synthesized. In the *E. coli trp* operon, for example, the peptide is made slowly if intracellular levels of tryptophan are low, and the antitermination structure is generated. The converse is true if tryptophan levels are high. In *B. subtilis* those leader sequences that have been analyzed do not contain an ORF. Moreover, transcription of *pur* and *pyr* gene clusters is also thought to be controlled by termination/antitermination, and it is unlikely these operons could be regulated by a mechanism precisely analogous to the *E. coli* system.

In the *B. subtilis trp* operon, attenuation is regulated in part by a *trans*-acting factor thought to be the product of the methyltryptophan resistance locus *mtr* (Shimotsu et al., 1986). Mutations in this gene result in constitutive expression of the *trp* genes. It is likely that the *mtr* product, when activated by tryptophan, binds to the leader region of the nascent mRNA in such a manner as to prevent formation of the antiterminator structure, thus favoring termination. In addition, binding of tryptophan-activated *mtr* gene product to already completed mRNA molecules is thought to inhibit the initiation of translation, thereby further reducing the production of *trp* enzymes (Kuroda et al., 1988).

Transcriptional regulation of the *pur* operon of *B. subtilis* shows some similarities to that of the *trp* system, but may be even more complicated. Synthesis of inosine monophosphate (IMP) is repressed by both adenine and guanine nucleotides, but apparently by different mechanisms. The latter are thought to promote premature cessation of transcription at a rho-independent termination site in the leader sequence, while adenine nucleotides appear to repress transcription initiation (Zalkin and Ebbole, 1988). It is thought likely that when purine levels are high, a guanine nucleotide activates a regulatory molecule, which in turn binds to the leader region of the nascent mRNA and blocks formation of the antiterminator secondary structure.

The products of polycistronic mRNAs are sometimes subunits in a common enzyme complex. In these instances, the polypeptides are required in 1:1 stoichiometry. Sequence analysis of the *trp* and *pur* operons shows that both are characterized by many gene overlaps; that is, the 3′-end of one coding sequence overlaps with the 5′-end of a contiguous downstream coding sequence (Henner et al., 1984; Ebbole and Zalkin, 1987). The overlaps are thought to result in "translational coupling" in which synthesis of one polypeptide from a polycistronic mRNA is at least partially dependent on the translation of the contiguous upstream gene. In some instances, this coupled translation is thought to result in 1:1 stoichiometric synthesis of the products of the overlapping genes.

Control of Catabolic Gene Expression

Members of the family Bacillaceae catabolize a wide variety of simple and complex organic compounds, including mono-and disaccharides, and polysaccharides such as starch which are partially digested by extracellular enzymes. As in the enteric bacteria, the structural genes for enzymes involved in degradation of these substrates are often clustered on the *Bacillus* chromosome. All operons so far studied are transcribed from σx^A promoters, and control of gene expression involves repressors and termination/antitermination systems (see Klier and Rapport, 1988, for a review).

The pathway involved in gluconate catabolism in *B. subtilis* is apparently regulated by negative control mediated by a repressor. Two inducible enzymes are required: the transport protein gluconate permease and gluconate kinase which phosphorylates gluconate. The genes for these functions, *gntP* and *gntK*, respectively, are part of a four cistron operon *gntR-gntK-gntP-gntZ*. Mutations that inactivate *gntR* are constitutive. This gene encodes a 243 amino acid protein thought to inhibit transcription by binding near the promoter located 40 bp upstream from *gntR* (Fujita and Fujita, 1987). Curiously, there is a five base overlap between the coding sequence of *gntR* and *gntK* suggesting there may be a translational coupling between these two proteins (Fujita et al., 1986). The genes required for the growth of *B. subtilis* on xylose polymers are also organized in a five cistron regulon, in which one of the genes, *xylR,* codes for a repressor that regulates expression of the entire gene cluster (Hastrup, 1988). Synthesis of the enzymes is induced by the presence of xylose in the medium. A repressor system has also been found to regulate the induction of penicillinase in *B. licheniformis* (Wittman and Wong, 1988).

Perhaps the most extensively studied catabolic system in the bacilli is that involved in sucrose catabolism. *B. subtilis* produces two β,D-fructofuranosidases, sucrase and levansucrase, after induction by sucrose. The former is an intracellular enzyme while the latter (which also cat-

alyzes the formation of the fructose polymer levan) is secreted (see Klier and Rapoport, 1988). The structural genes for sucrase, *sacA*, and that for levansucrase, *sacB*, are widely separated on the *B. subtilis* chromosome. The *sacA* gene is tightly linked to *sacP*, which is thought to be a membrane-associated protein that transports and phosphorylates sucrose. The *sacB* gene and the *sacA-sacP* cistrons are linked to regulatory loci, *sacR* and *sacT*, respectively. Mutations in either of the regulatory loci results in constitutive synthesis of the corresponding enzyme. The most extensive studies of the mechanisms of control have been made in *sacR*.

The *sacR* locus contains the *sacB* promoter. Between the transcription start site and the *sacB* coding sequence is a 199-bp region that is the target of several regulatory effectors of expression of the levansucrase gene (Aymerich et al., 1986). Part of this control is thought to involve a region of dyad symmetry that could form a transcription termination signal in the nascent mRNA. Deletion of this perspective terminator results in constitutive synthesis of levansucrase, and previously isolated constitutive *sacR* mutants map to this putative stem-and-loop structure (Shimotsu and Henner, 1986; Steinmetz and Aymerich, 1986). Messenger RNA synthesis is thought to stop at this terminator unless an antiterminator protein, presumably regulated by sucrose, interacts with the nascent RNA to prevent formation or to allow bypass of the loop. One candidate for the antiterminator maps to *sacS*, a genetic locus that affects both the synthesis of levansucrase and sucrase. The *sacS* locus consists of two cistrons, *sacY* and *sacX* (Aymerich and Steinmetz, 1987; Steinmetz et al., 1988; Zukowski et al., 1988). The *sacY* gene is thought to encode a sucrose-dependent antiterminator protein whose target probably is the region of secondary structure in *sacR*, where it presumably acts to prevent formation of the stem-and-loop. Deletion of *sacY* abolishes levansucrase synthesis. Current data suggest the *sacX* gene directs the production of a negative regulator of *sacY*; mutants in this cistron produce levansucrase constitutively.

The products of two other regulatory genes, *sacU* and *sacQ*, have been implicated in regulation of levansucrase synthesis. The target of the products of these genes also appears to be the *sacR* region, and they may serve to modulate the levels of gene expression (Shimotsu and Henner, 1986; Zukowski and Miller, 1986). *sacQ* encodes a 46 amino acid polypeptide which appears to stimulate the transcription of several secreted enzymes. Some mutations in *sacQ* lead to higher levels of expression of target loci, and genes thought to be similar to *sacQ* have been cloned from *B. licheniformis* and *B. amylolique-*

faciens. It now appears that the *sacQ* polypeptide is one of many small polypeptides which somehow regulate the transcription of degradative enzymes in the family Bacillaceae. Others may include the products of the *sacV*, *sin*, and *ptrR* genes (see Klier and Rapoport, 1988).

The enzymes for the histidase pathway responsible for the degradation of histidine are encoded in a cluster of four genes *hutH-hutU-hutI-hutG* in *B. subtilis*. Expression of this *hut* operon is induced by histidine and is also subject to catabolite repression. Between the σ^A promoter and the first gene, *hutH*, is a regulatory locus, *hutR*. The latter has been cloned and sequenced and found to contain two regions of possible regulatory significance (Oda et al., 1988). One is an ORF (ORF1) for a 151 amino acid protein that acts *trans* in heterozygotes to regulate the *hut* operon. A mutant having an amino-acid substitution in this protein has been isolated and found to be uninducible for the histidase pathway enzymes. This suggests that the ORF1 protein is a positive regulator in expression of the *hut* operon, although the possibility that the mutant is a superrepressor cannot be entirely excluded. The second regulatory region located between ORF1 and the first structural gene *hutH* (ORF2) is a region of dyad symmetry which could form a rho-independent terminator. It is possible that the product of ORF1, presumably activated by histidine, acts as an antiterminator to allow complete transcription of the *hut* operon.

The picture emerging from these and other studies suggests that regulation of catabolic pathways in *B. subtilis* involves a combination of repressors and positive controls through antitermination. It should be noted that in the attenuation systems observed in the biosynthetic pathways the leader sequences appear to be able to form two mutually exclusive secondary structures, one of which is the terminator. In the several leader sequences studied in catabolic pathways, only the terminator stem-and-loop is indicated. Thus, the putative antiterminator proteins in catabolic systems probably act by blocking formation of or allowing bypass of the terminator, rather than acting to favor one secondary structure over the other.

Catabolite Repression

Catabolic pathways in *Bacillus* are subject to catabolite repression by high levels of glucose and a variety of other rapidly metabolized substrates (Nihashi and Fujita, 1984). This phenomenon is of special interest in bacteria of this genus because sporulation is also repressed by glucose. In the enteric bacteria, catabolite

repression is mediated in part by the levels of cAMP and the interaction of this nucleotide with catabolite activator protein (CAP). However, cAMP apparently is not present in *Bacillus*, and thus could not be involved in catabolite repression in these organisms.

The promoters and associated control regions of many catabolic operons from *Bacillus* have been cloned and sequenced (Laoide et al., 1989; Melin et al., 1987; Oda et al., 1988). In some instances, these cloned regulatory systems, which for experimental purposes are sometimes fused to an indicator gene such as *E. coli lacZ*, continue to be subject to glucose suppression of transcription. Among the most thoroughly studied is the complex *amyR1-amyE*, the regulatory and structural genes for alpha-amylase of *B. subtilis*, and *amyR1-amyL*, the corresponding regulatory region and structural gene for alpha-amylase of *B. licheniformis*. Amylase synthesis is actually under two forms of regulation. One is a temporal control manifested by the fact that amylase genes are not fully induced until the onset of stationary phase. Temporal control may not occur in all *Bacillus* strains (Rothstein et al., 1986). In addition, in both *B. subtilis* and *B. licheniformis FDO2* production of alpha-amylase is repressed about 10-fold in glucose-containing cultures in early stationary phase, even when multiple copies of the complex are present on a plasmid (Laoide et al., 1989). Both forms of regulation are associated with the *amyR* regions. A plasmid-borne construct of *amyL* missing the promoter but including all transcribed sequences immediately adjacent and downstream from the promoter has been produced. When this fragment is attached at various distances from heterologous promoters, transcription continues to be subject to catabolite repression. This suggests the target of repression is not in the promoter itself or in regions upstream from it. One possibility is that a regulatory protein involved in mediating catabolite repression binds to a *cis*-acting site very close to the transcription start site, which in the case of *amyL* is only 29 to 31 nucleotides from the translation initiation codon (121 nucleotides for *amyE*). A search for consensus sequences downstream from several promoters of *B. subtilis* genes subject to catabolite repression has yielded a candidate sequence: 5′-ATTGTNA-3′ (Laoide et al., 1989). In the regulatory loci for *amyL* and *amyE*, this sequence is contained within an inverted repeat sequence that overlaps the transcription start site, and in the case of *amyL*, the translation initiation codon. A point mutation (*gra-10*) in this region of dyad symmetry relieves catabolite repression of *amyE* (Nicholson et al., 1987). In addition, Weickert and Chambliss (1989) have reported that deletion of DNA 3′ to

the *amyR1* promoter does not impair temporal activation of chloramphenicol acetyltransferase in *amyR1-cat86* transcriptional fusions, but abolishes catabolite repression.

Mutants of *B. subtilis* that are resistant to at least some manifestations of catabolite repression have been isolated. Among mutants originally selected for resistance to glucose-mediated repression of sporulation (Takahashi, 1979) is *crysA43*, which maps to rpoD, the structural gene for σ^A (Price and Doi, 1985). The alteration in σ^A in this variant also relieves catabolite repression in an *amyRi=lacZ* fusion cloned in *B. subtilis* (Laoide and McConnell, 1989). This may suggest a connection between the mechanism of glucose repression affecting sporulation and catabolite repression of at least those genes activated in stationary phase. In addition, Sun and Takahashi (1984) localized another catabolite-resistant mutation, *crysE1*, to the *rpo* operon. This locus encodes the β and β′ subunits of RNA polymerase. Taken together the two types of mutations occurring in subunits of RNA polymerase may suggest this enzyme is directly involved in catabolite repression or interacts with a protein, perhaps bound to the regulatory region, which mediates this phenomenon.

Resistance of Spores

The resting forms of bacteria are usually more resistant to various environmental stresses than their counterpart vegetative forms. The structure and composition of the resting (and dormant) form of endosporeforming bacteria, however, are quite different from other bacterial-resting forms (see Fig. 3). The core or protoplast containing the heat labile DNA, RNA, ribosomes, enzymes, and other proteins is surrounded by a primitive "germ cell wall." Moving toward the surface, there is a layer called the cortex which consists of peptidoglycan of a similar nature to that of the vegetative cell wall but with less cross linking in the peptides among other differences (Warth, 1978). A second cell membrane surrounds the cortex. The protoplast and cortex and their membranes are enclosed by layers of protein coat. A loose-fitting exosporium, appendages, and internal protein crystals may be found in some species.

Compared with vegetative cells, spores are more resistant to heat by a factor of 10^5 or more, to UV and ionizing radiation by 100-fold or more, and to desiccation, antibiotics, disinfectants, and other chemicals (reviewed by Roberts and Hitchins, 1969; Russell, 1982; Gould and Dring, 1974; Gould, 1983). Since spore resistance has been recognized for a long time and is important in food processing and sterilization

considerations, it has been extensively studied particularly with the genus *Bacillus*. Spore resistance to physical and chemical agents other than heat and irradiation indicated above is also noteworthy. Vegetative cells are killed at 88,000 p.s.i. for 14 h hydrostatic pressure while their spores have been shown to require 176,000 p.s.i. for the same time period (Gould and Dring, 1974). Spores are about 10,000 times more resistant to hyperchlorites than are vegetative cells. Two hundred roentgens (r) $\times 10^3$ of x-rays were required to kill 50% of treated *B. megaterium* spores, while 50% of treated *E. coli* cells were killed at 5.6×10^3 r. In every process designed for killing microorganisms, the spores are more resistant than vegetative cells and with few exceptions are the most resistant biological entities known. One exception is the nonsporeformer *Deinococcus radiodurans*, the most radiation-resistant organism yet discovered. Its resistance is presumably due to the possession of efficient repair mechanisms for radiation-induced changes in DNA.

The degree of heat resistance has been shown to depend not only on the species but also on the physiological environment in which the spores were formed. *B. stearothermophilus* spores are more heat resistant than *B. subtilis* spores which are more resistant than spores of *B. megaterium* (Roberts and Hitchins, 1969; Khoury et al., 1987). In addition, the spore resistance of each species depends on the temperature at which it was grown. For example, *B. subtilis* grown and sporulated at 20, 30, and 45°C produced spores having D_{90} values (the time required to kill 90% of the spores at 90°C) of 37, 78, and 99 min, respectively (Khoury et al., 1987). The spores were more temperature sensitive when formed in ethanol-supplemented media. Since temperature and ethanol are known to perturb the degree of order within membranes, this suggests that alteration of membrane function is an additional factor in the multifactorial nature of heat resistance. Other factors to consider in explaining heat resistance include protection of essential spore macromolecules (Murrell, 1981; Lindsay et al., 1985; Gerhardt and Marquis, 1989); specific effects of calcium dipicolinate (Lindsay and Murrell, 1986); mineralization (Marquis, 1989), and possibly foremost, dehydration (Gerhardt and Marquis, 1989). Current hypotheses on the heat resistance of endospores center on the dehydration of the protoplast (core) and the expandable cortex with its counterions (Gould, 1983). In the heat-resistant form, the spore coat is relatively impermeable to multivalent cations. The cortex (of high water content) contains an expanded electronegative peptidoglycan and mobile counterions exerting high osmotic pressure. The protoplast, of low water content, is osmotically dehydrated by the surrounding cortex and is, therefore, heat resistant. In the heat-sensitive form, there is a modified coat leaky to multivalent cations. The neutralized cortex, collapsed and free of counterions, exerts low osmotic pressure. The protoplast becomes partly hydrated and, therefore, heat sensitive. The theory of heat resistance, called the osmoregulatory expanded cortex theory, fits all the known facts but has yet to be proven or disproven. Germinated spores lose their heat resistance and yet, under special conditions, can be dehydrated to become both heat resistant and dormant once again (Gould, 1983). It is noteworthy that the heat resistance of some nonsporeformers can be increased in dehydrated cells. The expansion or contraction of the cortex is thought to account for the dehydrated state of the spore protoplast.

This reduced water content may also play a role in radiation resistance. It is thought that conformational differences between DNA in spore and vegetative cells may be associated with differences in hydration levels. The greater resistance of spores to UV radiation is also related to repair processes. The photoproduct formed during sporulation, 5-thyminyl-5,6-dehydrothymine (TDHT), is different from the thymine dimers formed in vegetative cells, both types of photoproducts being deemed as the cause of death. Dark repair mechanisms in germinating spores convert TDHT to thymine. The greater spore resistance to UV radiation is attributed to the more efficient removal of the unusual photoproduct (reviewed by Russell, 1982). However, as with the mechanism of spore heat resistance, the picture is complex and many factors are involved. For example, dipicolinic acid has been suggested as a protectant of spore DNA (Lindsay and Murrell, 1986) and it has been shown that the SASP may be involved (Setlow, 1988).

Likewise, explanations for ionizing radiation resistance of spores are not yet complete (Russell, 1982). Different spore DNA conformation (possibly due to dehydration), possession of coat layer radioprotectant substances, dipicolinic acid protection, and more efficient repair systems have all been implicated.

Spore coat layers, both coat protein and cortex, act as permeability barriers to toxic agents. At the present, this is the accepted explanation for the greater spore chemical resistance and resistance to lytic agents (Russell, 1982).

Spores as Biological Indicators

Endospores are often used as biological indicators. Known numbers of spores of various *Bacil-*

lus species of predictable death rate can be placed on various solid substrates (usually strips of filter paper) and placed with the items to be sterilized. The strips are then checked for retention of viable organisms by immersion into culture medium (various strategies are employed) after the sterilization process is completed if growth occurs then survival of the spores has occurred and hence the procedure for processing was inadequate. A D-value (decimal reduction time or time to kill 90% of the population at a particular temperature or treatment) of 3.0 min for *B. subtilis* spores is required for ethylene oxide sterilization (600 mg ethylene oxide per liter at 50% relative humidity and 54°C). For moist heat (121°C) *B. stearothermophilus* spores with a D-value of 1.5 min and for dry heat (170°C) spores of *B. subtilis* with a D-value of 0.8 min are preferred. *B. pumilus* spores (D-value of 0.17 Mrad) are used when ionizing radiation is used for sterilization (Korczynski, 1981).

Production of Antibiotics

Members of the genus *Bacillus* are capable of producing antibiotics as secondary metabolites in the late logarithmic or early stationary phase of growth of batch cultures. As many as 169 of these secondary metabolites have been recorded; for example, various strains of *B. subtilis* have been shown to produce 68 antibiotics while *B. brevis* can produce 23 (Katz and Demain, 1977). A partial updated listing modified from that of Katz and Demain (1977) is presented (Table 11) to illustrate that there are other *Bacillus* antibiotic producers. Most of the antibiotics are active against Gram-positive organisms, although there are exceptions. The majority are peptide antibiotics but some belong to other chemical classes (e.g., butirosin is an aminoglycoside and protocin is a phosphorus-containing triene). Also indicated in Table 11 are those antibiotics whose structural genes have been mapped and the few whose genes have been cloned. The latter types of studies are important in their own right and serve as models for the study of expression of the genes of other antibiotics.

A controversy has existed for some time concerning the function of these antibiotics. Since they usually appear upon the onset of sporulation, it has been proposed that they may be important factors in the transition of vegetative cells to spores (reviewed by Katz and Demain, 1977). Support for this hypothesis that

Table 11. Some *Bacillus* antibiotics.

Species	Antibiotic	Genes mapped	Genes cloned
B. subtilis	Subtilin[a]	+	+
	Surfactin[b]	+	−
	Bacilysin[a]	+	−
	Difficidin[c]	−	−

antibiotic production and sporulation may be regulated by the same or similar control mechanisms is now available. Transcription of the *B. subtilis tycA* gene (coding for tyrocidin synthesis) is dependent on the products of certain Stage 0 sporulation regulatory genes (Marahiel et al., 1987). Thus it does appear that the two physiological events are partially coupled to regulatory events occurring at the onset of sporulation.

In addition, it has recently been demonstrated that gramicidin S functions as an inhibitor of outgrowth after germination (Daher et al., 1985).

Protein Secretion

Members of the genus *Bacillus* are able to secrete a wide variety of enzymes into the culture medium (reviewed by Priest, 1977; Mezes and Lampen, 1985). Every *Bacillus* species which has been checked produces at least one extracellular enzyme. These include many different carbohydrates, several kinds of proteases, penicillinases, nucleases, phosphatases, lipase, phospholipase C, thiaminase, and bacteriolytic enzymes. A vast literature exists on the use of *Bacillus* enzyme models for studying secretion mechanisms, cellular location, and regulation. For some time, there has been considerable interest in producing large quantities of enzymes for industrial purposes—proteases for detergent supplementation, the brewing industry, various uses in the food industry and in leather manufacturing; and different amylases for brewery use, in bread making, and in the paper industry (see review by Debabov, 1982). Since many prokaryotic and eukaryotic genes can be fused to *B. subtilis*-derived regulatory regions and signal peptide sequences, such genetically manipulated organisms can be used for expressing and secreting many different heterologous proteins (for molecular cloning in *B. subtilis*, see Gryczan, 1982; Ganeson et al., 1982; Mezes and Lampen, 1985; Ganeson and Hoch, 1988). Interferon (Palva et al., 1983; Schien et al., 1986); human growth hormone (Honjo et al., 1986); and human interleukin-1 (Motley and Graham, 1988) are three such examples. However, yields of such proteins can be low, because extracellular neutral protease, subtilisin, esterases, and other proteases may degrade the secreted proteins. One strategy to overcome the problem and stabilize proteins has been to use strong glucose-insensitive promoters, protease deficient mutants, and catabolite repression of sporulation (Wong et al., 1986).

The widespread interest in protein secretion by *B. subtilis* has stimulated many studies on the genetics of secretion. There appears to be a general mechanism for regulating the synthesis of extracellular proteins. The activity of degradative enzymes can be increased by mutations at a number of loci that are unlinked to the structural genes for the affected enzymes. One family of genes, *senN*, *sacU*, *prtR* and *hpr*, codes for small regulatory proteins. For example, mutations at the *sacU* and *sacQ* loci can increase the expression of levan sucrase, alkaline protease, neutral protease, xylanase, betagluconase, alpha-amylase, and intracellular serine protease (Henner et al., 1988a). This type of stimulation of degradative enzymes is thought to be a global regulatory system turned on by a requirement for other carbon or nitrogen sources. The *SacU* product shares homology with other two-component sensorregulator systems (Ronson et al., 1987; Henner et al., 1988; Kunst et al., 1988).

Other Considerations

Just as *Bacillus* species have been important as models for studying differentiation or secretion, they have been employed extensively to study other important biological problems. These include DNA replication (Winston and Sueoka, 1982) and repair (Yasbin, 1985); chemotaxis (Ordal and Nettleton, 1985); genetic transformation (Dubnau, 1982); and translation apparatus (Smith, 1982; Hager and Rabinowitz, 1985).

CHAPTER 1.2.17

The Genus *Bacillus—Insect Pathogens*

DONALD P. STAHLY, ROBERT E. ANDREWS AND ALLAN A. YOUSTEN

Many different *Bacillus* species have been isolated from dead or dying insects. The *Bacillus* species commonly recognized as definite insect pathogens, however, are *B. popilliae*, *B. lentimorbus*, *B. larvae*, *B. thuringiensis*, and certain strains of *B. sphaericus* (de Barjac, 1981). These organisms, whose pathogenicity has been proved by fulfillment of Koch's postulates, are the subject of this review. The involvement of other *Bacillus* species in insect disease was reviewed by Krieg (1981) and several other authors in different chapters of the book *Microbial Control of Pests and Plant Diseases 1970–1980*, edited by H.D. Burges (1981).

Bacillus popilliae and Bacillus lentimorbus

B. popilliae and *B. lentimorbus* were named and described in 1940 by Dutky (1940). They are etiological agents of a naturally occurring disease of Japanese beetles, referred to as milky disease. The disease was so named because of the milky white appearance of the normally clear hemolymph of the diseased larvae (Hawley and White, 1935). The milkiness is due to the presence of very high numbers of spores of the bacteria; 2–5 $\times 10^9$ spores per larva or 2–5 $\times 10^{10}$ spores per ml (Dutky, 1940).

B. popilliae was named after the generic name of its host insect, the Japanese beetle, *Popillia japonica* Newman. The species *B. lentimorbus* was named by using the Latin adjective *lentus*, which means slow, and the Latin noun *morbus*, which means disease; literally, the slow disease (Dutky, 1940).

Both of these organisms have been used effectively for the biological control of the Japanese beetle (see Biotechnological Applications).

Habitats

Bacillus popilliae and *B. lentimorbus* are defined in nature as obligate pathogens according to the criteria of Bucher (1960). They are found only in association with a specific insect disease or in surrounding soil in the spore state. Both have a narrow host range, and in nature they probably grow only within the bodies of their host insects (Splittstoesser and Kawanishi, 1981). The host insects are all members of the order Coleoptera and the family Scarabaeidae.

Isolation, Growth, Maintenance, and Preservation of Cultures

These *Bacillus* species are isolated from hemolymph of infected beetle larvae where they occur as nearly pure cultures. Even when grubs of the Japanese beetle are co-infected with *B. popilliae* and *B. lentimorbus*, the diseased grubs prove to be infected with a single species, usually *B. popilliae* (Beard, 1946; Milner, 1981a).

To isolate, the grubs are first washed with water to remove most of the adhering soil, the surface is disinfected by immersion in 0.5% sodium hypochlorite (or 5% sodium hypochlorite [St. Julian et al., 1970]), the grub is rinsed, and the hemocoel is punctured with a dissecting needle. Hemolymph is then dripped into water. The spores can be freed of hemolymph by several alternating centrifugations and suspensions in water (Steinkraus, 1957a; Steinkraus and Tashiro, 1955).

Milner (1977) developed a useful, semiquantitative procedure for isolating a strain of *B. popilliae* (referred to as var. *rhopaea*) from soil. The procedure was based primarily on the observation that germination of *B. popilliae* spores was very slow in comparison to that of spores of other sporeformers. A soil suspension was made in a medium that promoted the germination of most spores except *B. popilliae*. The suspension was subjected to seven cycles of 40-min incubation followed by heating for 20 min at 70°C to kill germinated spores and vegetative cells. Further growth selectivity was provided by incubating the plated samples anaerobically (*B. popilliae* is facultative). Milner (1977) reported that about 15% of the *B. popilliae* spores in soil produced colonies and that a spore concentration of over 1.2×10^5 spores/g dry weight of soil could be quantified. Obviously, this procedure is very time consuming, and the possibility of quantitative error is great.

This chapter was taken unchanged from the second edition.

Both *B. popilliae* and *B. lentimorbus* are very fastidious. For example, neither will grow in nutrient broth, or if they grow, the growth is slight and ceases after three to four transfers following isolation from an insect host (Dutky, 1940). Spores or vegetative cells of both species can be grown on plates or in broth cultures of a variety of nutritionally rich, complex media. Two commonly used complex media are J-medium and MYPGP medium.

J-Medium for Growth of *B. popilliae* and *B. lentimorbus* (St. Julian et al., 1963)

Tryptone	5.0 g
Yeast extract	15.0 g
K_2HPO_4	3.0 g
Glucose (autoclaved separately)	2.0 g
Distilled water	to 1,000 ml

The pH is adjusted to 7.3–7.5. This medium may be solidified by inclusion of 20 g of agar.

MYPGP Medium for Growth of *B. popilliae* and *B. lentimorbus* (Costilow and Coulter, 1971)

Mueller-Hinton broth	10.0 g
Yeast extract	10.0 g
K_2HPO_4	3.0 g
Glucose (autoclaved separately)	0.5 g
Sodium pyruvate	1.0 g
Distilled water	to 1,000 ml

The pH is adjusted to 7.1. This medium may be solidified by inclusion of 20 g of agar.

Viable counts of vegetative cells or spores of *B. popilliae* and *B. lentimorbus* can be made by direct plating of suitable dilutions onto either of these media. The diluent should be either growth medium or 0.1% tryptone. Dilution in water or 0.85% NaCl leads to a rapid decline in viability (St. Julian et al., 1963). (If vegetative cells or spores are used to inject into grubs, the tryptone diluent is recommended because of the toxicity of growth medium [St. Julian et al., 1963].)

Inefficient germination and/or outgrowth complicates determination of spore numbers. It is common for 1 to 5% of microscopically visible spores to produce colonies. Aging of spores at 1–5°C (Splittstoesser and Farkas, 1966; Tashiro, 1957) or at room temperature (Milner, 1981a) provides some improvement. The other commonly used procedure is activation of germination by heating at 50°C for 15 min, although the effect is not dramatic. Sharpe et al. (1970) reported that 3.3% of microscopically visible spores of *B. popilliae* NRRL B-2309M produced colonies compared to 5.7% after 15 min of heating at 50°C. Heating at 60 to 80°C resulted in fewer colonies (St. Julian and Hall, 1968). St. Julian et al. (1967) suspended spores of *B. popilliae* in various solutions prior to heating at 50°C for 20 min and plating. Adenosine, L-alanine, and glucose, alone and in combination, had no effect on the plating efficiency. Also, KCl, NaCl,

$MnCl_2$, $CaCl_2$, $MgCl_2$, K_2HPO_4, and Na_2HPO_4 had little or no effect. Treatment of the spores with lysozyme, trypsin, and crude snail enzyme (from *Helix pomatia*) alone and in combination with various sugars had no effect. Splittstoesser and Farkas (1966) and Splittstoesser and Steinkraus (1962) reported that heating spores of *B. popilliae* at 60°C for 15 min in $CaCl_2$ (1 mM) at pH 7 caused about a 1,000-fold increase in colony count. This effect was prevented by KCl in concentrations as low as 10^{-6} M. There is no clear reason for the discrepancies between the results of the two groups with regard to heating in the presence of $CaCl_2$ and KCl. Perhaps the age of the spores was different. Splittstoesser and Farkas (1966) used spores freshly harvested from infected grubs. The age of the spores used by St. Julian et al. (1967) was not specified. Costilow and Coulter (1971) reported that spores of *B. popilliae* NRRL B-2309M heat shocked at 60°C for 15 min exhibited a plating efficiency of 60% when plated on the MYPGP medium as described above. Pyruvate was found to be important; when it was excluded from the medium, 7.7% plating efficiency occurred. Hrubant and Rhodes (1969) reported that treatment of spores of *B. popilliae* NRRL B-2309S with a crude extracellular enzyme produced by an unidentified *Bacillus* species (NRRL B-3425) increased the percentage germination from 8–16% to 36–43%. Splittstoesser et al. (1975) observed germination and outgrowth microscopically. They reported that more than 90% of spores of *B. popilliae* germinated and outgrew within 1 h when they were suspended in cabbage looper hemolymph and tyrosinase (quantity not specified), at an alkaline pH (unspecified) at 37°C.

Cells of *B. popilliae* and *B. lentimorbus* can be maintained in the vegetative state by transferring cultures from J-medium or MYPGP agar to fresh medium once every 7 to 10 days. The plates or tubes should be incubated at 30–33°C until pinpoint colonies are present, and then refrigerated. Gordon et al. (1973) employed monthly transfers of *B. popilliae* in tubes of J-medium without glucose and to which 0.1% agar was added and incubated at 25°C for the entire month. For *B. lentimorbus*, stock cultures were maintained in a biphasic medium (Haynes and Rhodes, 1963) on a shaker at 25°C. Equal volumes of $2 \times$ J-broth without glucose and 4% agar were sterilized separately. The agar was allowed to solidify and the broth was then added. Inoculum (5%) was transferred every 2 weeks.

The most convenient way to maintain cultures for long periods of time is to make use of the natural longevity of spores. Washed spore suspensions can be added to dry, sterile soil, smeared on glass microscope slides and dried,

or kept as suspensions (in water or alcohol) (Milner, 1981a; St. Julian et al., 1978). Another way of maintaining cultures is to spread hemolymph from infected grubs directly (without washing the spores) onto slides and to air-dry them (Milner, 1981a). The problem with these approaches is that spores are formed reproducibly only by infection of their host larvae (see "Ecophysiology; Growth and Sporulation In Vitro," this chapter).

Lyophilization has been used to preserve vegetative cells of *B. popilliae* and *B. lentimorbus*. Haynes et al. (1961) scraped cells of both species from agar-solidified medium and suspended them in bovine serum prior to lyophilization. Lingg et al. (1967) prepared cells for lyophilization by suspending them in a solution containing 5% sodium glutamate and 0.5% gum tragacanth.

Identification

No phylogenetic studies have been conducted on *B. popilliae* and *B. lentimorbus*. From the taxonomic studies that have been conducted, mainly based on phenotypic observations, these species do belong in the genus *Bacillus* (Claus and Berkely, 1986). They are rod-shaped, endospore-formers (with swollen sporangia) that have a typical Gram-positive cell wall structure (Black, 1968a, 1968b), the latter as observed by electron microscopy. (Actually, the Gram-staining reaction is reported to be negative except during the sporulation process.) They are facultative organisms, although they grow much better aerobically (Sharpe, 1966). One characteristic that makes these two species (and *B. larvae*) unusual members of the genus *Bacillus* is that they lack catalase. All other members of the genus, except *B. azotoformans* and some strains of *B. stearothermophilus*, are catalasepositive (Claus and Berkeley, 1986).

B. popilliae and *B. lentimorbus* are very similar, both causing milky disease in a restricted group of beetles belonging to the family Scarabaeidae. Of 42 phenotypic characteristics recommended by Claus and Berkeley (1986) for differentiation of *Bacillus* species, these two species share all but two; only *B. popilliae* produces a parasporal crystalline inclusion and is capable of growth in 2% NaCl. [The latter characteristic may be strain variable; Milner (1974) reported that a strain he refers to as *B. popilliae* var. *rhopaea* has a parasporal body but is incapable of growth in 2% NaCl.] Kaneda (1977) divided 19 *Bacillus* species into six groups based on fatty acid composition. *B. popilliae* and *B. lentimorbus* were placed in group B with *B. larvae* and *B. polymyxa* (see The Genus *Bacillas—Nonmedical* in this Volume). This group's fatty acids consisted of less than 3% unsaturated fatty acids. The predominant (39–62%) fatty acid was the anteiso-C_{15} acid (range of chain length; 14–17) (Kaneda, 1969, 1977).

Dutky (1940) noted that there was a noticeable difference in the diseases caused by *B. popilliae* and *B. lentimorbus*. *B. popilliae* caused "type A milky disease," in which the infected grubs became increasingly white and opaque during the course of the infection. During the last stage of the disease, just before death, the grubs exhibited a slight brownish tinge. *B. lentimorbus* caused "type B milky disease." This disease state was superficially the same as type A in infected grubs found in late summer and fall. In grubs infected in the fall that survived until spring, however, a marked difference was noted, the color of these grubs turned a muddy brown. This darkening was due to extensive formation of blood clots, which are brown to black. Clots that accumulated in appendages blocked the insects' circulation, leading to a blackened, gangrenous condition of the affected parts. The biochemical basis of this clotting phenomenon is unknown.

Other differences between *B. popilliae* and *B. lentimorbus* have been reported. They differ in lipid composition (Bulla et al., 1970a; Kaneda, 1969), and they differ somewhat in the surface topography of their ridged spores (Bulla et al., 1969). Hrubant and Rhodes (1968) showed that antisera in rabbits presumably against surface antigens of B. popilliae and *B. lentimorbus* (the cells were incubated overnight at 4°C in 0.85% NaCl and 0.5% phenol before use as antigens). Antiserum against *B. popilliae* showed no cross-reaction in agglutination tests against *B. lentimorbus* cells and vice versa. Conversely, antisera made in rabbits against sonicated vegetative cells of both species showed significant cross-reaction in double diffusion assays and immunoelectrophoresis (Krywienczyk and Luthy, 1974).

Other data that are sometimes of taxonomic value relate to the type of peptidoglycan (Schleifer and Kandler, 1972) and the major type of quinone (Collins and Jones, 1981) possessed by cultures. Comparative data on *B. popilliae* and *B. lentimorbus*, however, are lacking. The *B. lentimorbus* peptidoglycan is of the direct cross-linked *meso*-diaminopimelate type [from Ranftl (1972) as cited by Schleifer and Kandler (1972)]. No information exists on the peptidoglycan type of *B. popilliae*. The major quinone possessed by *B. popilliae* is a menaquinone with seven isoprene units (MK-7), but no information exists on the quinone(s) possessed by *B. lentimorbus* (Hess et al., 1979).

From the above and other data, it is understandable that differences of opinion have arisen concerning the taxonomy of these bacteria. Claus and Berkeley (1986), Gordon et al. (1973), and Krieg (1961) have preferred to consider

these two as separate species, giving weight to the presence or absence of the parasporal body. Krywienczyk and Luthy (1974), Milner (1981a), and Wyss (1971) have given more weight to characteristics other than the parasporal body, and, thus, consider it more appropriate to refer to "*B. lentimorbus*" as *B. popilliae* var. *lentimorbus* and "*B. popilliae*" as *B. popilliae* var. *popilliae*.

Species names other than *B. popilliae* and *B. lentimorbus* have been proposed for some milky disease isolates. A bacterium was isolated in 1956 by Beard from an Australian Scarabaeidae, specifically *Heteronychus sanctae-helenae* Blanch, that had a milky disease. A very similar strain, referred to as *B. lentimorbus* var. Maryland, was studied by Tashiro and Steinkraus (1966) and Steinkraus and Tashiro (1967). Beard (1956) believed that his isolate differed sufficiently in morphology and in host specificity from *B. lentimorbus* that it deserved separate species status; he called it *B. eulomarahae*. The sizes of the vegetative cell rods and the spores of both Beard's isolate and *B. lentimorbus* var. Maryland are 0.3 × 3 µm and 0.2–0.4 µm in diameter, respectively. This compares to the corresponding dimensions of *B. lentimorbus* (Dutky, 1940) of 1×5 µm and 0.9×1.8 µm, respectively (Beard, 1956). These are rather significant differences. Studies on many more strains, including use of molecular taxonomic techniques, are required before this species designation should be officially recognized.

A separate species designation was also given to a culture isolated from a milky diseased common cockchafer grub (*Melolontha melolontha* Linneaus) in Switzerland by Wille (1956); i.e., *Bacillus fribourgensis*. Hurpin (1966) isolated another culture from a diseased grub of *M. melolontha* in France, and designated it as *B. popilliae* var. *melolontha*. These two cultures were reported to be essentially identical in appearance of the parasporal body, in their ability to grow and sporulate in tissue cultures of *Phyllophaga anxia* hemocytes (Lüthy et al., 1970), in their antigenic composition based on double diffusion and complement fixation (Lüthy and Krywienczyk, 1972), and in their nutritional requirements (Wyss, 1971). They differed from the original *Bacillus popilliae* isolate of Dutky (1940) in host specificity, virulence for *M. melolontha* L. by different routes (Hurpin, 1967), nutritional requirements (Wyss, 1971), and a lower maximal growth temperature (33°C as compared to 37°C for *B. popilliae* Dutky) (Wyss, 1971). Most investigators agree that separate varietal status is probably more appropriate than separate species status.

Milner (1974) in Australia isolated a parasporal body-containing strain of *B. popilliae* from *Rhopaea verreauxi* that differed from both the Dutky (1940) strain (which he referred to as *B. popilliae* var. *popilliae*) and *B. popilliae* var.

melolontha. It differed in host specificity (Milner, 1974, 1976), maximum growth temperature (32°C) (Milner, 1974), the ability to use carbohydrates and salicylic acid (it cannot use fructose and salicylic acid, compounds used by the other two varieties) (Milner, 1974; Wyss, 1971), and the inability to grow in 2% NaCl (Milner, 1974).

Other strains of milky disease-causing bacteria exist that possess parasporal bodies that should be investigated for possible varietal status in the species *B. popilliae*. Dumbleton (1945) in New Zealand isolated a culture from *Odontria zealandica* White that differs from *B. popilliae* var. *popilliae* in the shape of the parasporal body and in host specificity. White (1947) and later Adams (1949), Harris (1959), and Dutky (1963) studied milky disease in *Cyclocephala borealis*, the northern masked chafer. The *Bacillus popilliae* strain isolated from this species is unusual in host specificity and in having large and sometimes multiple parasporal bodies. Recently Boucias et al. (1986) found that milky disease of a serious sugarcane pest in Florida, *Cyclocephala parallela* Casey, was caused by *B. popilliae*. Fowler (1972, 1974) isolated a *B. popilliae* strain from the New Zealand grass grub *Costelytra zealandica* and White (1986) in India isolated a strain of *B. popilliae* referred to by Milner as *B. popilliae* var. *holotrichia* from *Heterodera* (= *Holotrichia*) *consanguinea* (Blanchard), a grub that causes damage to sugarcane and other wet-season crops. Feng et al. (1982) in China studied a strain of *B. popilliae* designated SH-m5 that has pathogenicity for *Holotrichia oblita* Fald., *Anomala corpulenta* Mots., and *Exolontha serrulata* (Gyllenhal).

Probably different varieties also exist in the species *Bacillus lentimorbus*. For example, Beard (1956) in Australia referred to a culture that he isolated from milky diseased *Sericesthis pruinosa* (Dalm.) as *B. lentimorbus* var. *australis*. It differed from the originally isolated *B. lentimorbus* (Dutky, 1940) in host specificity. Other strains that should be studied include a strain lacking a parasporal body that was isolated from the New Zealand grass grub *Costelytra zealandica* (Fowler, 1972, 1974), strain RM17 isolated in Australia from *Aphodius tasmaniae* (Milner, 1981b; Milner and Beaton, 1981), and the strains isolated by Boucias (1986) in Florida from *Ligyrus subtropicus* Blatchley, the worst pest of Florida sugarcane. Investigations on taxonomy of *Bacillus lentimorbus* have definitely been hampered by the difficulty in growing the organism. Some strains, for example RM17 mentioned above (Milner, 1981b), have not yet been cultivated on artificial media.

In conclusion, considerable confusion exists concerning the appropriate nomenclature for milky disease bacteria. It is not clear whether *B. popilliae* and *B. lentimorbus* should be consid-

ered separate species. Varietal designations may or may not be appropriate. Phage typing would aid in these considerations but no phages active on these organisms have been discovered. Immunological techniques have only been used to a small extent. Molecular taxonomic approaches would be of great value with regard to these issues. For example, De Ley (1978) states that to belong to a single species, cultures should have GC contents that vary by no more than 2%. The reported GC content of *B. lentimorbus* and *B. popilliae* are 37.7 and 41.3mol%, respectively (reference is not an exact match-Manichini et al., 1968), thus suggesting that separate species designation is appropriate. This conclusion is rendered less certain by the report of Fahmy et al. (1985) that the GC values for the same strain of some *Bacillus* species published by different investigators varied widely (up to 14%). Nucleic acid hybridization would be of even greater value than DNA base composition, but no data exist for *B. popilliae* and *B. lentimorbus*. It is perhaps appropriate to maintain separate species status, as has been done by the authors of the section on *Bacillus* species in the current edition of *Bergey's Manual of Systematic Bacteriology* (Claus and Berkeley, 1986), until more comparative data have been obtained.

Ecophysiology

NUTRITION. Both *B. popilliae* and *B. lentimorbus* are very fastidious. Most of the media in common use employ yeast extract, casein digest, and a carbohydrate, the latter reported to be essential for growth as an energy source (Bulla et al., 1978; Rhodes et al., 1966). Defined synthetic media have been developed (Sylvester and Costilow, 1964; Wyss, 1971). Thiamine is essential for growth, a discovery first made by Dutky (1947, 1963). Biotin, although not essential, is stimulatory for growth. Eleven amino acids are essential and three are stimulatory. Purines and pyrimidines are not required. Sylvester and Costilow (1964) reported that inclusion of barbituric acid is required for growth in their medium. The role of barbituric acid is unknown (Coulter and Costilow, 1970; Sylvester and Costilow, 1964).

Carbohydrates that can be used by all varieties of *B. popilliae* and *B. lentimorbus* tested include glucose, galactose, mannose, maltose, and trehalose (Milner, 1974; Steinkraus and Tashiro, 1967). All varieties tested except for *B. popilliae* var. *rhopaea* use fructose (Milner, 1974). No hydrolysis of starch, casein, or gelatin occurs (Claus and Berkeley, 1986).

These bacteria are facultative, but their growth is greatly enhanced by the presence of oxygen, as will be discussed below (see "Metabolism" this chapter).

GROWTH AND SPORULATION IN VIVO. The normal route of infection of these microbes is by feeding. St. Julian et al. (1970) described the infectious process as occurring in four phases: 1) during the first two days no bacteria are present in the hemolymph; 2) vegetative proliferation predominates from day 3 to day 5; 3) from day 5 to day 10 vegetative growth and sporulation occur concomitantly; and 4) the last phase, which usually terminates with insect death by day 14 to 21, is characterized by massive sporulation. As indicated previously, the number of spores at the time of death is as high as 5×10^{10}/ml. The insect grub continues feeding and appears normal until near death.

The most detailed description of how the bacteria migrate from the grub's intestinal tract into the hemolymph deals with infection by *Bacillus popilliae* var. *popilliae* of the European chafer, *Amphimallon majalis* (Splittstoesser et al., 1973; Splittstoesser et al., 1978). The spores germinate in the hindgut and vegetative cells are transported to the midgut by antiperistalsis. Here the vegetative cells penetrate the epithelial cells lining the midgut, mostly at the anterior end. This penetration seems to be by a phagocytosis-like event. Nothing is known about the mechanism of attachment that must precede phagocytosis. Perhaps the glucose- and mannose-containing capsular polysaccharide (Li et al., 1985) is involved. At the area of intracellular intrusion, hemocytes aggregate to form an inflammatory capsule on the hemocoel surface of the digestive tract. Considerable bacterial cell death occurs during this intracellular migration but a few viable cells pass into the hemolymph where they proliferate and sporulate. Once in the hemolymph, no phagocytosis by hemocytes occurs. Splittstoesser et al. (1973) indicated that bacilli tend to concentrate in connective tissue sheaths or in close contact with hemocytes during the sporulation process. Schwartz and Townshend (1968) reported that *B. popilliae* spores and vegetative cells in hemolymph of Japanese beetle larvae are also not phagocytized. They noticed no effect of the bacteria on hemolymph coagulation or on the number of hemocytes.

In the case of *B. thuringiensis*, the parasporal body alone causes most of the disease symptoms and may also aid in bacterial penetration to the hemocoel. With milky disease caused by *B. popilliae*, there is no such clear evidence. *B. lentimorbus* causes a disease that is almost identical to that caused by *B. popilliae*, and has no parasporal inclusion. Weiner (1978) isolated parasporal bodies from *B. popilliae* and determined that they were proteinaceous in nature. Whole or alkali-solubilized parasporal bodies fed to third-instar larvae of Japanese beetles were not toxic. Injection of solubilized parasporal bodies did cause death. Solubilized parasporal protein of

B. popilliae var. *melolonthae* also causes loss of viability of *Melolontha melolontha* primary hemocyte cultures (Lüthy et al., 1976).

The precise cause of death is also not understood. Dutky (1963) observed that thiamine present in the hemolymph of healthy Japanese beetle larvae was absent in hemolymph of milky-diseased larvae. This observation led him to speculate that larval death was due to starvation for essential nutrients. Lüthy (1986) speculated that death is simply due to general exhaustion coured by the heavy infection. There is a possibility that one or more toxins may be involved since cell-free filtrates of cultures of *B. popilliae* are lethal upon injection (Dutky, 1963). The toxic component(s) is inactivated by heating at 50°C for 10 min. It is unknown whether this toxin(s) is elaborated in vivo. Sharpe and Detroy (1979) found that the fat bodies of Japanese beetle larvae infected with *B. popilliae* were reduced in weight about 75% from those of healthy larvae. They suggest that this depletion may cause death simply by preventing progress to the pupal stage.

One approach used to gain an understanding of conditions promoting growth and sporulation in the larval hemolymph of Japanese beetles was to determine changes that occurred in the hemolymph during the development of milky disease caused by *B. popilliae*. The results from a decade of research, including references to many publications, were published in a review by Bennett and Shotwell (1973), and will not be discussed in this review, except as they relate to the subsequent discussion of metabolism (see "Metabolism," this chapter).

Growth and Sporulation In Vitro. Growth of *Bacillus popilliae* is exponential in most complex media used. After the maximum population is attained, there is usually a very rapid decline in cell viability with little or no sporulation occurring (Rhodes et al., 1966). The lack of efficient sporulation in vitro has been the major factor limiting the usefulness of these bacteria for insect control (see "Biotechnological Applications" this chapter). Only spores can be used for biological control, because of the rapid loss of viability in soil that occurs with vegetative cells.

Steinkraus and Tashiro (1955) were the first to obtain sporulation of *B. popilliae* and *B. lentimorbus* in vitro. Their strategy was based on the hypothesis that sporulation was induced by nutrient deficiency. They transferred cells growing on a complete solid medium to the surface of an agarsolidified starvation medium as a paste. Some sporulation occurred, but the spores fed to larvae were reduced in virulence. In a separate study, no significant sporulation of *B. popilliae* occurred in European chafer hemolymph, mac-erated larvae, or larval extracts (Steinkraus, 1957b). (Efficient sporulation occurs in the hemolymph of viable larvae of this insect host.)

Rhodes et al. (1965) obtained up to 0.3% sporulation of *B. popilliae* by the use of a solid medium that contained yeast extract, sodium acetate, potassium phosphate, and agar. The strain used was a derivative of strain NRRL B-2309, referred to as NRRL B-2309S, because it was isolated from a smooth colony on acetate agar. Addition of glucose or trehalose repressed sporulation. Sporulation frequency was unchanged by addition of soil extract, Japanese beetle hemolymph, or larval extract. It was later found that they could occasionally obtain between 10^5 and 10^7 spores/ml of this strain in liquid J-medium supplemented with 1.0% charcoal (Haynes and Rhodes, 1966; Haynes and Rhodes, 1969). The brand and specific batch of charcoal (Haynes et al., 1972), yeast extract (Haynes and Crowell, 1973), and tryptone (Haynes and Crowell, 1973) were crucial. Haynes and Whih (1972) reported that it was important to use spores from the previous culture of strain B-2309S as inoculum. Use of vegetative inocula resulted in loss of ability to sporulate. It is unknown whether spores of B-2309S are infective by feeding; they are by injection (St. Julian and Bulla, 1973).

Sharpe et al. (1970) isolated another strain of *B. popilliae*, referred to as NRRL B-2309M, from strain B-2309S. They developed an MYPT medium containing Mueller-Hinton broth, yeast extract, potassium phosphate, and trehalose that supported fair sporulation (up to 1.5×10^6 spores/ml). Sporulation was improved when the medium was filter-sterilized, and best when on solid MYPT medium (Sharpe et al., 1970; Sharpe and Rhodes, 1973). Asporogenic sectors frequently appeared in colonies. Although strain B-2309M sporulates fairly well in vitro, the spores are not commercially useful because they are infective for Japanese beetle larvae only by injection, not by feeding (Schwartz and Sharpe, 1970; Sharpe et al., 1970).

Costilow and Coulter (1971) developed MYPGP agar medium (see "Isolation, Growth, Maintenance, and Preservation of Cultures," this chapter), that supported 12% sporulation of *B. popilliae* NRRL B-2309M. The pyruvate in the medium was shown to be essential for sporulation.

Costilow et al. developed a broth medium and cultural conditions that resulted in the production of refractile bodies in cells of *B. popilliae* and *B. lentimorbus* that were not mature spores but could be premature, abortive spores (Costilow et al., 1966; Mitruka et al., 1967). Spores and the refractile bodies ("Costilow Bodies") of *B. popilliae* were similar in RNA, DNA,

and protein content. Refractile bodies did not contain dipicolinic acid, whereas spores contained 1.9% dipicolinate. Catalase, although absent from vegetative cells, was present at low levels in both spores and refractile bodies (Mitruka et al., 1967).

Yousten et al. (1974) attempted, without success, to obtain sporulation of *B. popilliae* NRRL B-2309 by resuspension of postexponential phase cells of *B. popilliae* in glucose-supplemented spent broth prepared from a sporogenous strain of *B. subtilis*. Although unsuccessful, this approach was reasonable, particularly since the recent discovery of the extracellular factor(s) produced by *B. subtilis* that is required for efficient sporulation (Grossman and Losick, 1988).

Sporulation up to 50% was reported to occur when *B. popilliae* var. *melelontha* was grown in tissue culture medium with hemocytes of *Phyllophaga anxia* larvae (a June beetle) (Lüthy et al., 1970) or hemocytes of *Melolontha melolontha* larvae (Lüthy et al., 1976). The spores were infective by feeding. *Bacillus popilliae* NRRL B-2309 (var. *popilliae*) grew but did not sporulate in either of these systems. Although the above results are promising, tissue culture techniques are too laborious and expensive to be useful for mass production of spores (Lüthy et al., 1976).

Results recently reported by Feng et al. (1982) are promising. They claim to have observed 50–60% sporulation when *B. popilliae* SH-m5 was cultured in J-broth supplemented with thiamine-HC1 (0.01 g/l). Moreover, the spores produced in vitro were infective by feeding as well as by injection into larvae of three different species: *Holotrichia oblita* Fald., *Anomala corpulenta* Mots., and *Exolontha serrulata* (Gyllenhal).

METABOLISM. *Bacillus popilliae* and *B. lentimorbus* are facultative microbes but their growth is definitely enhanced in the presence of oxygen. Sharpe (1966) showed that the growth of *B. popilliae* in a fermenter was optimal at an aeration rate of 0.5 vol/vol/min (vvm), an air-flow equivalent to an oxygen absorption rate of 0.5 mmol of oxygen/l/min. Weiner (see Rhodes, 1965) measured the dissolved oxygen concentration during growth of *B. popilliae* in a fermenter. As growth proceeded, a large drop in dissolved oxygen occurred. When growth was complete (and cell viability decreased) the dissolved oxygen concentration increased to a normal value. The hemolymph of healthy Japanese beetle third-instar larvae has a dissolved oxygen concentration of 0.078–0.1 μmol/ml (Weiner et al., 1966). When vegetative cells are abundant, a 36–53% drop in dissolved oxygen occurs, followed by a return to a normal level as sporulation proceeds (Weiner et al., 1966).

There are some indications in the literature that sporulation of *B. popilliae* is somewhat oxygen sensitive. The rapid loss in viability commonly observed (Rhodes et al., 1966) when growth of *B. popilliae* in liquid media is complete obviously precludes efficient sporulation. Costilow et al. (1966) reported that cessation of shaking at the end of the growth phase decreased the death rate. Sharpe et al. (1970) obtained optimal sporulation of *B. popilliae* NRRL B-2309S by incubating cells in MYPT broth with shaking for 3 days followed by no shaking for 10 to 15 days. The fact that sporulation occurs best on solid rather than in broth media may also be due to the reduced oxygen microenvironment, which is undoubtedly present when oxygen-metabolizing cells are so closely packed together. Oxygen is required for sporulation (Sharpe et al., 1970; Sharpe and Rhodes, 1973), but there may be a critical stage that requires reduced oxygen concentration.

B. popilliae, in addition to being catalase-negative as determined by the loop test, also lacks NADH peroxidase (Pepper and Costilow, 1965). Costilow and Coulter (1971) did detect some catalase in spores, but the activity was thousands-fold less than that in more common *Bacillus* species such as *B. subtilis* (Dingman and Stahly, 1984). Pepper and Costilow (1965) and Costilow et al. (1966) hypothesized that in *B. popilliae* the production of H_2O_2 during the stationary phase may be responsible for the rapid loss of viability and consequent absence of sporulation. Cell extracts of late exponential or early stationary phase cells produce H_2O_2 via a soluble NADH oxidation system (Pepper and Costilow, 1965). Attempts to prevent loss of viability by addition of catalase to cultures have been unsuccessful (Costilow et al., 1966; Steinkraus, 1957b). However, this finding does not rule out the possibility that intracellular H_2O_2 accumulation is responsible for the loss of viability. In larval hemolymph, the oxygen concentration may be poised perfectly so that the amount of available oxygen is adequate to provide the energy needed for sporulation but not enough to favor H_2O_2 accumulation. One other enzyme required for protection against oxygen toxicity is superoxide dismutase, the enzyme that catalyzes the conversion of superoxide (O_2-) to H_2O_2 and O_2. Superoxide dismutase is produced by *B. popilliae* at an activity level approximately equivalent to that of *Escherichia coli* (Costilow and Keele, 1972). Only a single form of superoxide dismutase is synthesized in *B. popilliae* (Yousten and Nelson, 1976) and it is induced by aerobic growth (Yousten et al., 1973).

Both *B. popilliae* and *B. lentimorbus* oxidize glucose, primarily to acetate and lactate. Small amounts of glycerol and ethanol and traces of

acetoin and acetaldehyde accumulate (Pepper and Costilow, 1964). The ratio of acetate to lactate produced by *B. popilliae* increases with increased aeration. Cells incubated anaerobically do not catabolize glucose. Glucose is catabolized by both *Bacillus* species solely by the Embden-Myerhof-Parnas (EMP) and the pentose phosphate (PP) pathways (Bulla et al., 1970b; Pepper and Costilow, 1964). Under normal aeration, glucose is catabolized by *B. popilliae* primarily (75–98%) by the EMP pathway (Bulla et al., 1970b; Pepper and Costilow, 1964). When the cells are aerated with 100% oxygen, 60% of the glucose is oxidized via the EMP pathway and 40% by the PP pathway (Pepper and Costilow, 1964). When *B. popilliae* cells were harvested from hemolymph of infected Japanese beetle larvae during growth and sporulation, they catabolized 75% of the glucose by the PP pathway and 25% by the EMP pathway; a pattern opposite from that existing for cells grown in vitro (St. Julian et al., 1975). It is possible that the oxygen concentration in vivo is the factor that favors the PP pathway, but one or more different control mechanisms may be operative.

In larvae, glucose is not the major carbohydrate used by these bacteria. Trehalose (α-D-glucopyranosyl-α-D-glucopyranoside) is the major carbohydrate in Japanese beetle hemolymph. It is present at very high concentrations, about 0.7%, a concentration that inhibits vegetative growth of *B. popilliae* in vitro (Bennett and Shotwell, 1973). This fact led Bennett and Shotwell (1973) to speculate that trehalose might be present in hemolymph in a bound form to be released as needed by the pathogen. During sporulation in vivo, the concentration of trehalose is reduced to between 0.1 and 0.47% (Bennett and Shotwell, 1973). Thus, there is a significant concentration of trehalose present during sporulation. Although in vitro sporulation of *B. popilliae* NRRL B-2309S is repressed by trehalose (Rhodes et al., 1965), it is possible that trehalose is actually required for in vivo sporulation. Trehalose is transported into cells by a phosphotransferase system using phosphoenolpyruvate (PEP) as the phosphoryl donor (Bhumiratana et al., 1974). [The uptake mechanism used for glucose transport is unknown. No PEP-glucose phosphotransferase has been detected (St. Julian et al., 1975).] The intracellular transported form of trehalose, 6–0-phosphoryl-α-D-glucopyranosyl-α-D-glucopyranoside, is cleaved to glucose and glucose 6-phosphate by phosphotrehalase, a reaction first detected in *B. popilliae* (Bhumiratana et al., 1974). The intracellular level of PEP may regulate the uptake of trehalose. PEP is more likely to accumulate when the EMP pathway is used rather than the PP pathway. Thus, Bulla et al. (1978) proposed that perhaps the dependence on the EMP pathway by in vitro grown cells results in excessive accumulation of PEP, which, in turn, results in excessive intracellular accumulation of trehalose that represses sporulation.

Most *Bacillus* species oxidize glucose to pyruvate, lactate, or acetate during growth. When the glucose is gone, growth ceases, synthesis of enzymes of the tricarboxylic acid (TCA) cycle is induced, and the acids that accumulated during growth are oxidized to CO_2 and H_2O (Hanson et al., 1963, 1964; Nakata and Halvorson, 1960). *B. lentimorbus* NRRL B-2522 and *B. popilliae* B-2309 cells grown in vitro or in vivo (*B. popilliae* only) were not capable of oxidizing acetate (Bulla et al., 1971; McKay et al., 1971; St. Julian et al., 1975). Pepper and Costilow (1964) reported that a variant of strain B-2309, strain B-2309 PA, was able to oxidize acetate. This oxidation occurred at the end of the exponential growth phase. McKay et al. (1971) showed that several other variants of strain B-2309 also were able to oxidize acetate and they presented evidence in support of the existence of a complete TCA cycle. Although some of these strains are oligosporogenic in vitro, the strains that oxidize acetate most rapidly do not sporulate in vitro (McKay et al., 1971). It is possible that operation of a TCA cycle is not required for sporulation in vivo. The constant supply of trehalose during sporulation may serve as an adequate energy source (Bulla et al., 1978).

Genetics

A problem that complicates scientific study and commercial use of these organisms is the presence of genetic instability. The loss in ability to sporulate after prolonged cultivation on artificial media is a commonly observed phenomenon. Sharpe and Bulla (1978) reported that *Bacillus popilliae* NRRL B-2309 cells when plated yielded three different colonial variants, each of which exhibited a different generation time. Each colony type reverted to a mixture of all three types, but the tendency was to transform to the fastest growing variant, which proved to be noninfective when injected into Japanese beetle larvae. There seemed to be a correlation between slow growth rate and virulence.

Practically nothing is known about the genetics of these organisms. No conjugation or transduction system is known. In fact, no phages have been discovered that infect these bacteria. Bakhiet and Stahly (1986) developed a protoplast transformation system that was effective in permitting the transformation of plasmid pHV33 into *B. popilliae* NRRL B-2309S, but the frequency of transformation was so low that transformation attempts were often unsuccessful.

One finding that facilitated production of protoplasts was that cell walls of *B. popilliae* are degraded by mutanolysin; they are resistant to lysozyme (Bakhiet and Stahly, 1985a). Development of a more efficient method of transformation will be a significant step toward gaining an understanding of the genetics of these organisms.

The only published information on plasmids present in these species is the report of Faust et al. (1979) that there are two plasmids present in the strain of *B. popilliae* isolated from spore powder produced by Fairfax Biological Laboratory, Inc., Clinton Corners, New York.

D. W. Dingman (personal communication) found that chromosomal DNA of *B. popilliae* (nine strains) and *B. lentimorbus* (one strain) is resistant and sensitive to restriction by *Mbo*I and *Dpn*I, respectively. Chromosomal DNA of each of seven other *Bacillus* species is restricted by *Mbo*I but not *Dpn*I. This is evidence for the presence of ^{6}N-methyl adenine in the GATC sequences in DNA of *B. popilliae* and *B. lentimorbus*. Modification of this sequence is presumed to occur by a DNA methylase which functions like the *dam* methylase of *E. coli* (Marinus and Morris, 1973; Lacks and Greenberg, 1977).

Biotechnological Applications

B. popilliae and *B. lentimorbus* have been used effectively for the biological control of the Japanese beetle. The Japanese beetle was so named because it was first known to exist only in Japan. In 1916, Dickerson and Weiss of the New Jersey Department of Agriculture discovered several grubs (larvae) of the Japanese beetle in a nursery in the state of New Jersey, USA. It was speculated (Fleming, 1968) that they were imported in soil surrounding the rhizomes of Japanese iris. Since that time they have spread throughout almost all of the USA east of the Mississippi River. They have also "hitch-hiked" to the northwestern USA, Europe, and Australia.

Japanese beetle larvae eat the roots of grass (yards and pastures), ornamental plants, and garden or truck crops. Adult Japanese beetles eat leaves, flowers, and fruit of trees, ornamental and floral plants, citrus fruits, berry crops, garden vegetables, and farm crops (including corn, soybeans, clover, and alfalfa) (Klein, 1981). In 1982 the total cost for prevention, treatment, and replacement related to turfgrass damage alone in the USA was estimated to be $234 million (Ahmad et al., 1983). This cost does not include the extensive damage caused by the adult beetle, and omits some damage costs caused by the larval form of the beetle.

From 1939 to 1953 a massive program, involving USA federal and state governments, was carried on to accelerate the spread of *B. popilliae* throughout the area infested by the beetle (Fleming, 1968). Adequate biological control of the beetle was attained in much of the area at the time when the program ceased. Serious problems still occur today, however, and the spread of the Japanese beetle to new areas continues.

Spores for the government-subsidized program were produced in vivo; i.e., by the artificial infection of Japanese beetle larvae. Until recently this was also true for commercially available products. Fairfax Biological Laboratory, Inc. (Clinton Corners, NY) continues to obtain their spore preparations from spores generated in vivo. Ringer Corp. (Minneapolis, MN) is producing spores in vitro by use of a patented procedure (Ellis et al., 1989) purchased from Reuter Laboratories, Inc. (formerly of Haymarket, VA). However, their product, Grub Attack®, contains *Bacillus polymyxa* rather than *B. popilliae*. Also, all four strains deposited with the American Type Culture Collection (Rockville, MD) in connection with the patent are not *B. popilliae*. The preferred production strain, ATCC 53256, is *B. polymyxa* and the other strains (ATCC 53257, 53258, and 53259) are *Bacillus amylolyticus* (D. Stahly, unpublished observations).

Other areas of interest relate to the mechanism of pathogenicity and factors regulating host specificity of different strains (Klein, 1981). Research in these areas will undoubtedly aid and strengthen the biotechnological application of these bacteria.

Bacillus larvae

Bacillus larvae was named and described in 1906 by G. F. White, who provided evidence by experimental inoculation that this bacterium caused a fatal disease of honey bee larvae called American foulbrood (White, 1907). Maassen (1906) in Germany and Burri (1904) in Switzerland isolated cultures from larval remains that were named *B. brandenburgiensis* and *B. burri* (Cowan, 1911), respectively. These cultures later proved to be identical to White's isolate. Nomenclatural priority has been given to White. The only known host for *B. larvae* is the honey bee, *Apis mellifera* Linnaeus.

The use of the term "American" in "American foulbrood" is somewhat misleading because the disease occurs throughout the world. The term "foulbrood" is derived from the odor of decaying larvae (brood), described as resembling that of burned glue.

American foulbrood is a very serious disease in part because the bacteria sporulate in the larval remains so that the spores [more than 10^9

spores per larva (Holst, 1946; Shimanuki, 1980)], which are stable for at least 35 years (Haseman, 1961), are left to infect other larvae. When a colony is determined to be infected, government regulations require that the colony be destroyed (most commonly accomplished by burning). Shimanuki (1980) estimated that about 3% of all colonies inspected in the USA are infected with American foulbrood. The direct loss to U.S. apiaries from lost honey and beeswax (based on a total annual value of these products of $132 million [reference is not an exact match Levin, 1984]) is about $4 million. This is a minor part of the total loss, however. It was estimated that in 1985 the value of the increased yield and quality of U.S. crops due to honey bee pollination was $9.3 billion (Robinson et al., 1989a, 1989b). Accordingly, the value of the lost pollination (3%) would be $279 million.

Habitats

The major source of *B. larvae* is the larval remains of honey bees in honeycombs. In a hive infected with American foulbrood, spores of *B. larvae* can also be isolated from the honey, wax, pollen, and hive walls (Gochnauer, 1981; Shimanuki and Knox, 1988).

Isolation, Growth, Maintenance, and Preservation of Cultures

Usually, *B. larvae* can be easily isolated from larval cadavers, since they commonly are present as almost pure cultures (Holst, 1945; Sturtevant, 1924). The relative lack of other organisms suggested to Holst (1945) that *B. larvae* might produce an antibiotic. Indeed, he found that one or more antibiotics were produced during sporulation that were effective against a variety of Gram-positive and Gram-negative species.

Sturtevant (1924) isolated pure cultures from diseased larval cadavers simply by suspending a small amount of the dried remains in water and then streaking a loop of the suspension onto a solid medium.

Rose (1969) developed a method for isolating *B. larvae* from a mixture of other bacteria, including spore-formers. His method is based on the fact that *B. larvae* spores, unlike those of most other sporeformers, do not readily germinate in nutrient broth (Rose, 1969; White, 1906). A few drops of an aqueous suspension of dried larval cadavers were added to a tube of nutrient broth and the tube was heated at 70°C for 15 min. Then it was incubated at 37°C for 12 h. Two additional heat treatments with an intermediate incubation were used before plating on a medium permitting germination of *B. larvae* spores and growth.

Shimanuki and Knox (1988) developed a method for determining the number of *B. larvae* spores in honey. Problems with honey are its high viscosity and the presence of antibacterial substances. Their procedure, in brief, involved heating the honey at 45°C to decrease its viscosity, diluting with water, dialysis, centrifugation, resuspension of the pellet in water, heating at 80°C for 10 min to kill vegetative cells, and plating on a solid medium. By use of this method they showed that *B. larvae* spores were present in 30% of beekeeper-packed honey and 100% of commercial-packed honey (blended from many sources).

Spores or vegetative cells of *B. larvae* can be grown on a variety of solid or liquid media. The medium used by Gordon et al. (1973) was the J-medium (St. Julian et al., 1963), described above for growth of *B. popilliae* and *B. lentimorbus*. Another medium that is satisfactory for the routine growth of *B. larvae* is "modified MYPGP medium", similar to the MYPGP medium described above.

Modified MYPGP Medium for Growth of *Bacillus larvae* (Dingman and Stahly, 1983)

Mueller-Hinton broth	10 g
Yeast extract	15 g
K_2HPO_4	3 g
Glucose (autoclaved separately)	2 g
Sodium pyruvate	1 g
Distilled water	to 1,000 ml

This medium may be solidified by inclusion of 20 g of agar.

When these or other solid media are used for determination of spore count, cultures are first heated at 65°C for 15 min to kill vegetative cells (Dingman and Stahly, 1983; Rose, 1969). A problem with spore counts is the low plating efficiency observed. Dingman and Stahly (1983) reported that heat-resistant counts were usually about 6% of the direct microscopic spore counts. The explanation for this discrepancy is unknown. Heat shocking of spores of *B. larvae* NRRL B-3650 at 60–80°C before plating promoted little to no increase in plating efficiency (Dingman, 1983).

B. larvae cultures can be maintained by growth on either of the above agar solidified media at 30–37°C for 2–3 days. Plates or slants are stored at 4°C and transferred every 2 weeks.

Frozen spore stocks are the most convenient for long-term culture preservation. Most *B. larvae* cultures exhibit low percentage sporulation when grown on J-agar or modified MYPGP agar at 37°C. Vegetative cells can be preserved by conventional lyophilization or by suspension in a freezing medium (e.g., 70-ml Hanks' 1 × medium, 10-ml rabbit serum, 20 ml glycerol) and storage at −70°C.

Identification

No phylogenetic or molecular genetic studies have been performed on *B. larvae* other than an analysis of the nucleotide composition of its DNA; the type strain DNA has a GC content of 50 mol%, based on buoyant density (Nakamura, 1984).

Phenotypic observations indicate that *B. larvae* belongs in the genus *Bacillus* (Claus and Berkeley, 1986). The cells are rod shaped, and endospores are formed within swollen sporangia. No parasporal inclusions have been observed. The vegetative cells have a typical Gram-positive cell wall structure (Bakhiet and Stahly, 1985b). The endospores have a smooth surface, and the inner spore coat is somewhat unusual in that it consists of seven distinct lamellae (Bakhiet and Stahly, 1985b; Bulla et al., 1969).

Some strains are motile by peritrichous flagella. "Giant whips" are often microscopically observed in these strains (Gochnauer and L'Arrivee, 1969a; White, 1907). These were thought to be due to flagella actively discharged from the cells and in an aggregated state (Frank and Hoffman, 1968; Gochnauer and L'Arrivee, 1969a). Ludvik et al. (1983) observed by electron microscopy that in old sporulating cultures cell wall material separates from the cell surface in the form of thick filaments. They observed that the "giant whips" formed when free flagella aggregated with this material.

Other characteristics that are often of value in speciation are type of cell wall peptidoglycan (Schleifer and Kandler, 1972), cellular lipid composition (Kaneda, 1977), and major type of quinone present (Collins and Jones, 1981). Nothing is known about the type of cell wall peptidoglycan possessed by *B. larvae*. Based on lipid composition, Kaneda (1977) placed *B. larvae* in group B (out of six groups in the genus *Bacillus*) together with *B. popilliae*, *B. lentimorbus*, and *B. polymyxa*. The major quinone possessed by *B. larvae* is a menaquinone with seven isoprene units (MK-7). A minor amount of MK-3 is also present (Hess et al., 1979).

Bacillus larvae is similar to *B. popilliae* and *B. lentimorbus* in that it is fastidious. It does not survive serial transfer in nutrient broth. It is a facultative bacterium but it grows much better aerobically (Dingman and Stahly, 1984; Lochhead, 1928). Similar to *B. popilliae* and *B. lentimorbus*, *B. larvae* lacks catalase activity, as measured by observation of oxygen bubbles when a small drop of 10–30% H_2O_2 is applied to the colonies (Haynes, 1972). The catalase test is probably the most helpful diagnostic tool to use after initial isolation of the microbe, in addition to colony appearance.

The many other phenotypic characteristics of *B. larvae* that differentiate it from other *Bacillus* species are reviewed by Claus and Berkeley (1986) and will not be discussed here except as they relate to possible varietal diversity within the species. Jelinski (1985) conducted a study of biochemical reactions of 110 strains of *B. larvae* from five sources. The strains were uniformly positive or negative for most tests. They were variable for nitrate reduction (58% of strains positive), acid production from mannitol (17% positive), and acid production from salicin (11% positive). If denitrification is actually occurring in the positive strains, then the difference between the positive and negative cultures might be sufficient to at least consider varietal differentiation. However, it has not been established that denitrification occurs in the positive strains. No published studies have indicated whether better growth occurs anaerobically in the presence or absence of nitrate. No studies have indicated whether nitrous oxide or nitrogen, products that normally result from denitrification, are produced by the positive strains. The other variable traits may or may not be significant from the perspective of a genetic relationship. Obviously, GC content and nucleic acid hybridization data are needed.

Immunological studies have been performed by several investigators. Antisera against *B. popilliae* and *B. lentimorbus* showed some cross-reaction in agglutination assays with *B. larvae* (Hrubant and Rhodes, 1968). Giauffret et al. (1970) demonstrated some cross-reaction in precipitation and immunofluorescence between *B. larvae* and *B. alvei*. Cross-reaction between *B. larvae* and *B. alvei* was not observed in immunodiffusion and immunofluorescence assays conducted by Peng and Peng (1979). Otte (1973) reported that antiserum against *B. larvae* produced little to no cross-reaction with 36 strains of other bacteria by immunofluorescence. Preliminary results of Giauffret et al. (1970) indicated that there are some important serological differences between strains of *B. larvae*, but more detailed investigations are needed to determine if varietal differentiation is justified.

Bacteriophage typing has been employed for varietal differentiation of *B. thuringiensis* and *B. sphaericus* strains. Several temperate phages of *B. larvae* have been isolated by different investigators (see "Genetics," this chapter). Some strains of *B. larvae* are sensitive, and some are immune (or resistant). Some of the strains are immune simply because they possess the same or related phages in the prophage state (Bakhiet and Stahly, 1988; Dingman et al., 1984; D. P. Stahly, unpublished observations). It is not clear, however, whether some of the cases of resistance are an indication of more basic cellular differ-

ences between *B. larvae* strains. More research is required before it can be determined whether phage typing will be of value for varietal differentiation.

Ecophysiology

NUTRITION. As stated previously, *Bacillus larvae* is fastidious, failing to grow on nutrient agar. This characteristic led early investigators to supplement their usual media with many different natural substances: e.g., macerated, healthy bee larvae (White, 1906); calf or pig brain extract (Maassen, 1908); egg yolk (White, 1919); egg yolk and yeast (Sturtevant, 1924); yeast extract and carrot extract (Lochhead, 1933); and minced chicken embryo (Tarr, 1937a). In 1942 Lochhead found that thiamine replaced all of these special requirements. His basic medium consisted of glucose, peptone, thiamine, K_2HPO_4, and various salts. Foster et al. (1950) found that poor growth occurred in the complex medium of Lochhead (1942) unless it was pretreated with charcoal, supplemented with starch, or a combination of the two. Their hypothesis is that anti-growth substances were removed or sequestered from the medium. Katznelson and Lochhead (1948) attempted to develop a synthetic medium for *B. larvae*. In addition to thiamine, a purine, either xanthine or guanine, was required. However, when a basal salts-glucose medium was supplemented with 18 amino acids, thiamine, and a purine, growth sufficient for serial transfer only occurred when the medium was made semisolid with agar.

B. larvae is capable of catabolizing the carbohydrates glucose, fructose, galactose, trehalose, glycerol, mannose, and ribose. Use of mannitol, xylose, sucrose, and salicin is strain variable (Azuma and Kitaoka, 1965; de Barjac, 1981; Jelinski, 1985; Lochhead, 1928).

B. larvae is facultative but grows much better in the presence of oxygen (Bailey, 1968). Bailey and Lee (1962) inoculated tubes containing a semisolid medium with spores of *B. larvae* and, after incubation, observed growth in a band (sometimes two bands) 5–10 mm below the surface. The authors concluded that the spores germinated and grew best under microaerophilic conditions. Dingman (1983) observed similar banded growth after inoculating semisolid medium with vegetative cells. The evidence of Bailey and Lee (1962) may not relate to the oxygen requirement for germination, as claimed, since it is possible that germination occurs at positions in the tubes other than where growth occurs.

GROWTH AND SPORULATION IN VIVO. Larvae of honey bees become infected by ingestion of spores of *B. larvae*. Spores are the only infective form (Tarr, 1937b), probably because vegetative cells are rapidly killed by royal jelly, the food material in which the larvae are immersed (Holst, 1946). When vegetative cells of *B. larvae* were suspended in royal jelly (10^7 cells/ml), < 10 viable cells/ml remained after 30 s at room temperature (N. Bakhiet and D. P. Stahly, unpublished observations). The bactericidal effect, due primarily to 10-hydroxy δ^2-decenoic acid (Blum et al., 1959), is apparently diminished or absent in the midgut, where the spores germinate and grow.

The larvae are very susceptible to infection only up to an age of about 1.5 days. After 1.5–2 days of age they become totally resistant (Bamrick, 1964; Bamrick and Rothenbuhler, 1961; Hoage and Rothenbuhler, 1966). Davidson (1973) studied the histopathology of American foulbrood and in the process discovered a possible mechanism for the age-related development of resistance. She determined that vegetative cells in the midgut lumen invaded the peritrophic membrane by a phagocytosis-like process, traversed the epithelium, and entered the hemocoel, where they grew to high populations and caused a generalized septicemia. The first barrier, the peritrophic membrane, although present in larvae as young as 8 h, increases tremendously in thickness and "density of composition" with age (Davidson, 1970, 1973). Davidson suggested that this structural change may contribute to the age-related resistance. Nothing is known about the mechanism of attachment of *B. larvae* cells to the peritrophic membrane that must precede phagocytosis. Perhaps the glucose, mannose, and galactose-containing capsular polysaccharide (Li et al., 1985) is involved.

Death usually occurs at an age of 8 to 11 days; 2 days before or after the transition to the pupal stage. As stated above, death is preceded by growth in the hemolymph to high populations and a general invasion of most body tissues. Davidson (1973) reported heavy infection of the fat body and rupture of hemocytic membranes. The dead larvae rapidly decompose as *B. larvae* exhibits massive sporulation.

The question of whether a toxin or an enzyme of *B. larvae* is involved in pathogenicity is an open one. Aqueous extracts of cadavers of larvae killed by American foulbrood are toxic by feeding to honey bee larvae (Patel and Gochnauer, 1959). Such larval remains have a high level of protease activity (Holst and Sturtevant, 1940; Patel and Gochnauer, 1959), suggesting that protease activity and toxicity are related. Heating of the extract for 1 min at 100°C inactivated both protease activity and toxicity (Patel and Gochnauer, 1959). Holst and Sturtevant (1940) demonstrated protease activity only in sporulat-

ing cultures of *B. larvae*. Furthermore, certain asporogenic mutants did not produce protease. These facts led Bamrick (1964) to question involvement of proteases in the disease process; he suggested that their involvement was probably in postmortem decomposition, a process that occurred simultaneously with the appearance of spores. Gochnauer (1969) and Patel and Gochhauer (1972) separated multiple (two to three) proteases from cells at different stages of development. One enzyme, stated to be associated with "vegetative cells," was obtained from cells in cultures that were 3–10 days old; probably stationary-phase cells. Protease excretion by other *Bacillus* species occurs early in the sporulation process, at a time coincident with the beginning of the stationary phase (reviewed by Freese and Heinze, 1983). Since proteases are normally excreted early in sporulation, it is possible that proteases might be involved in late pathological changes in larvae, even before refractile spores are visible. The availability of a protease-minus, spore-plus mutant would aid in analyzing this question. Proteases are not involved in the initial, early penetration of *B. larvae* of the peritrophic membrane and epithelial cells. This conclusion is supported by the observation of Davidson (1973) that penetration of the peritrophic membrane is not accompanied by physical evidence of enzymatic digestion of the membrane.

Sporulation In Vitro. Whereas *Bacillus larvae* sporulates efficiently in the hemolymph and other tissues of bee larvae, most strains sporulate very poorly in or on artificial media. The study of American foulbrood has been slowed somewhat by the difficulty of obtaining large numbers of spores in vitro. Interest about in vitro sporulation is heightened by the possibility that what is learned about sporulation in *B. larvae* may, in part, be applicable to the other catalase-minus insect pathogens, *B. popilliae* and *B. lentimorbus*.

Sporulation has been reported to occur at a higher frequency in cells grown on solid media rather than in broth media. A variety of solid media has been used which promotes sporulation of *B. larvae* (Azuma and Kitaoka, 1965; Bailey and Lee, 1962; Dingman and Stahly, 1983; Foster et al., 1950; Gordon et al., 1973; Lochhead, 1928; Smith et al., 1949). Azuma and Kitaoka (1965) indicated that they obtained sporulation by growth on slants in tubes "closed tightly with rubber stoppers"; an indication that the sporulation process may be somewhat oxygen-sensitive.

Gochnauer (1969) and Gochnauer and L'Arrivee (1969a) used a biphasic system to obtain sporulation. The bottom phase consisted of Difco brain-liver-heart agar. The top phase was a shallow layer of broth medium of the same components as the bottom phase (except agar) or a yeast extract, starch, and potassium phosphate medium (Bailey and Lee, 1962). Cultures were incubated at 35°C for 5–10 days without shaking.

There are only three reports of fair-to-good sporulation in single-phase, liquid media. St. Julian and Bulla (1971) obtained 2×10^7 spores/ml of the type strain, *B. larvae* NRRL B-2605, in liquid MD medium, which contains yeast extract, glucose, and K_2HPO_4. Gochnauer (1973) obtained 10^8 spores/ml after incubation with gentle shaking of *B. larvae* 34A in brain heart infusion broth plus thiamine hydrochloride. Dingman and Stahly (1983) obtained 5×10^8 spores/ml after incubation with gentle shaking of *B. larvae* NRRL B-3650 in TMYGP broth, which contains tris-maleate buffer, yeast extract, glucose, and sodium pyruvate. The level of aeration was critical to achieve sporulation of strain B-3650; aeration was required, but at a level much reduced from that used to obtain sporulation of more typical *Bacillus* species. This finding is consistent with the observation of Fitz-James and Young (1969) that sporulation of *B. larvae* was inhibited by excess shaking.

Lodesani et al. (1985) used a rather nontraditional method to obtain sporulation of strains that sporulate poorly if at all on solid media. A culture was grown in a broth medium, cells were concentrated by centrifugation and suspension in a small volume of phosphate buffer, and the suspension was placed in a sterile dialysis bag suspended in a broth medium containing yeast extract, potassium phosphate, and starch. The culture was incubated without shaking at 34°C for 30 days. The authors stated that, depending on the strain, 10–80% of the cells introduced into the dialysis bags sporulated.

Metabolism. Aspects of metabolism discussed below deal with oxygen metabolism, protection against toxic forms of oxygen, pathways of glucose catabolism, and nutrient requirements for sporulation.

Bacillus larvae, when grown in the presence of air, consumes oxygen as would be expected (Dingman and Stahly, 1984). Most oxygen-utilizing bacteria possess superoxide dismutase to protect against superoxide (O_2^-) and catalase and/or peroxidase to protect against H_2O_2. *B. larvae* NRRL B-3650 resembles *B. popilliae* and *B. lentimorbus* in that it has superoxide dismutase levels approximately equal to those of *B. subtilis* 168, a "typical" *Bacillus* species, but lacks NADH peroxidase and has very low catalase activity (Dingman and Stahly, 1984). Catalase activity is nondetectable during growth. It appears during the early stationary phase and

increases during the time of appearance of refractile spores. The activities at these two stages are about 2,700 and 5,400 times less than those exhibited by *B. subtilis*. The relative absence of catalase (and NADH peroxidase) may be the cause of the apparent oxygen-sensitivity of sporulation (Dingman and Stahly, 1983). *B. larvae* does not accumulate H_2O_2 extracellularly, but intracellular accumulation remains a possibility (Dingman and Stahly, 1984).

Mylroie and Katznelson (1957) reported that *B. larvae* metabolizes glucose primarily to acetate during the exponential growth phase. They demonstrated the presence of enzymes of both the Embden-Meyerhoff-Parnas pathway and the pentose phosphate pathway. In an extension of this work, St. Julian and Bulla (1971) showed that key enzymes of the Entner-Doudoroff pathway, as well as those of the other two pathways, are present in *B. larvae* NRRL B-2605. This is rather unusual since the Entner-Doudoroff pathway has not been demonstrated in other *Bacillus* species, and the pathway rarely occurs in Gram-positive bacteria. Radiorespirometric analysis, however, indicates that the Entner-Doudoroff pathway is not being used to a significant extent; the pentose phosphate pathway is the primary pathway used.

No information exists on how glucose is transported into cells; no phosphoenolpyruvate: glucose phosphotranferase activity has been detected (St. Julian and Bulla, 1971). Also, no information exists on the mechanism of uptake and catabolism of trehalose, the main carbohydrate in honey bee larval hemolymph.

St. Julian and Bulla (1971) showed that glucose degradation by *B. larvae* NRRL B-2605 occurs during growth, resulting in a decline in pH due to acid (probably acetic acid) accumulation. When growth ends coincident with depletion of glucose from the medium, the pH increases. This pH increase is due to complete oxidation of acetate through the citric acid and glyoxylic acid cycles.

The pattern of glucose utilization by *B. larvae* NRRL B-3650 is surprisingly different from that described above for the type strain (NRRL B-2605) (Dingman and Stahly, 1983). Strain B-3650 does not degrade glucose during growth; glucose oxidation begins at the end of exponential growth. The only component of TMYGP broth required for growth of strain B-3650 is yeast extract. Acids were produced during growth, presumably from yeast extract components of the TMYGP broth (see "Ecophysiology; Sporulation In Vitro," this chapter). Thus, glucose usage in this strain may be regulated by a type of catabolite repression. Another unusual property of strain B-3650 is that both glucose and pyruvate are required for sporulation. In most

Bacillus species glucose represses sporulation. Glucose is needed by strain B-3650 for a late event(s) in sporulation; it could be added as late as 35 h (25 h after the end of exponential growth) without any decline in the number of spores formed. (Spores are first apparent at 45 h.) This requirement can be partially satisified by substitution of glucosamine or potassium gluconate, but not by galactose, fructose, mannitol, or glycerol. Why pyruvate is required for sporulation is not readily apparent. Pyruvate is depleted from the medium before sporulation begins. Substitution of acetate, lactate, citrate, glutamate, or succinate does not satisfy this requirement (Dingman, 1983; Dingman and Stahly, 1983).

Genetics

Bacillus larvae exhibits instability with regard to sporulation ability and virulence. Tarr (1937b) reported that serial transfer on an artificial medium resulted in loss of ability to sporulate. Holst and Sturtevant (1940) observed frequent asporogenic sectors in colonies. Stahly and Livasy (unpublished observation) have made similar observations with *B. larvae* NRRL B-3650. Asporogenic colonies remained asporogenic; i.e., the change was not reversible. Shimanuki et al. (1965) indicated that virulence of *B. larvae* was increased by passage three times through honey bee larvae. To understand these and other phenomena, an understanding of the genetics of *B. larvae* is highly desirable.

Conditions have been developed for polyethylene glycol-mediated plasmid transformation and phage DNA transfection of protoplasts (Bakhiet and Stahly, 1985a; Chen and Yin, 1986). Although several phages have been isolated from *B. larvae* (see below), no reports of transduction exist. Also, there have been no reports of conjugation.

Three morphologically distinct temperate bacteriophages have been isolated from *B. larvae*. PBL1, originally isolated from *B. larvae* NRRL B-3553 by Gochnauer (1955, 1970), has been purified and characterized (Dingman et al., 1984; Gochnauer and L'Arrivee, 1969b). Based on comparative electron microscopic data, phage BLA, isolated by Drobnikova and Ludvik (1982), is a PBL1-like phage. PBL1-like phages are very common in *B. larvae* strains isolated from different geographical locations within the USA (D. P. Stahly, unpublished observations). Another temperate phage, PBL0.5, was isolated from strain NRRL B-3558 (Dingman et al., 1984) and characterized (Bakhiet and Stahly, 1988). An apparently identical phage, PBL2, was isolated from strain NRRL B-3553, where it was found to coexist in the prophage state with PBL1 (Bakhiet and Stahly, 1988). It is probable that

phage BL2, isolated by Benada et al. (1984b), is a PBLO.5-like phage; a conclusion based on comparative electron microscopic data. A morphologically distinct temperate phage, PBL3, was isolated from *B. larvae* GA and was partially characterized (Campana, N. Bakhiet, and D. P. Stahly, unpublished observations). It is hoped that these phages will be of value for phage typing and, perhaps, for development of a transduction system(s). None of the phages PBL1, PBL0.5, and PBL3 produced plaques on a variety of other *Bacillus* species, including *B. popilliae* (H.-W. Ackermann, personal communication; D. Takefman and D. P. Stahly, unpublished observations).

The only published information on plasmids in *B. larvae* is that of Benada et al. (1984a). They found cryptic plasmids in three of 12 strains tested.

Preliminary evidence suggests that a restriction-modification system exists in strain NRRL B-3555 (Bakhiet and Stahly, 1985).

Bacillus thuringiensis

Bacillus thuringiensis is a Gram-positive, facultative, sporeforming, rod-shaped bacterium that has been the subject of intense investigation in laboratories worldwide. As a member of the genus *Bacillus*, the organism shares with the other members of the taxon the ability to form endospores that are resistant to inactivation by heat, desiccation, and organic solvents. Biochemically, sporulation in *B. thuringiensis* is very similar to that in other sporeforming bacteria and the spores resemble those of other bacilli in morphology and composition. However, the formation of one or more parasporal crystalline bodies adjacent to the spore during stages III to V of sporulation distinguishes *B. thuringiensis* from most other *Bacillus* species (Andrews et al., 1982, 1987; Bulla et al., 1985).

B. thuringiensis is probably best known as an insect pathogen. Older cultures, which contain spores and parasporal crystals, are highly toxic to larvae of members of certain insect orders. This property has caused extensive interest in this organism because of the potential to use it to formulate more effective, specific, and environmentally safe insecticides (Bulla et al., 1985).

Although *B. thuringiensis* is capable of saprophytic existence in soil, it is also a frank insect pathogen. Not surprisingly, the initial discovery of *B. thuringiensis* was as an insect pathogen, since its pathogenicity made its existence in the environment more obvious. Probably the first description of *B. thuringiensis* was by Ishiwata, who, in 1901, described the etiological agent of "sotto disease" or "flacherie." Signifi-

cantly, Ishiwata was also the first to describe the relationship between the culture's age and pathogenicity. Young cultures of the "sotto disease bacillus," as he termed his isolate, were not as pathogenic to larvae of the Japanese silk moth, *Bombyx mori,* as were older cultures (Bulla et al., 1980; Ishiwata, 1901).

Probably the first to suggest the use of *B. thuringiensis* for controlling insect pests was Berliner (1911, 1915), who, apparently independently of Ishiwata, described the causative agent of a disease of the Mediterranean meal moth, *Anagasta kuhniella.* Berliner, and later Mattes, described the crystalline inclusion body, or "Restokorper," within sporulated cells, and it was Berliner who first used the species name *thuringiensis,* deriving the name from the German province of Thuringia (Bulla et al., 1980).

As reviewed by Andrews et al. (1987), from the initial discovery of the microbe until the early 1950s, numerous studies appeared in the literature aimed at using *B. thuringiensis* in insect control without sufficient basic information to accomplish these goals. In the early 1950s, investigators began studying the basic biology of *B. thuringiensis* and considering some fundamental properties of its insect pathology. Steinhaus (1951), for example, published an electron micrograph of the crystal toxin, and in 1953 Hannay described the development of the crystal toxin in relation to the sporulation cycle. Hannay (1953) and Hannay and Fitz-James (1955) observed that the diamond-shaped crystals or parasporal bodies are composed primarily of protein and suggested that the crystals might be involved in the establishment of septicemia in insect larvae. Angus (1956a, 1956b) prepared toxic filtrates that included crystals alone and crystals plus spores and showed that the crystals were responsible for midgut paralysis and cessation of feeding, whereas the spores were required for septicemia.

Habitats

Bacillus thuringiensis is a member of a limited group of bacteria that occurs both naturally and can be added to an ecosystem to achieve insect control. A somewhat arbitrary distinction is made between "natural" and "artificial" habitats of *B. thuringiensis*. A habitat is defined as natural when *B. thuringiensis* can be isolated when there is no previous record of application of the organism to that ecosystem. A habitat is considered artificial, on the other hand, when there has been previous application of the organism for insect control. It is important to note that, in the latter case, artificial and natural may not be mutually exclusive; *B. thuringiensis* may occur naturally in

environments where additional organisms have been applied.

Most *B. thuringiensis* cultures that have been studied were either isolated directly from infected insects or from soil associated with them. The spores of *B. thuringiensis* readily persist in soil and vegetative growth occurs when nutrients are available. All of the early isolates were pathogenic for insects and this pathogenicity became recognized as a differentiating characteristic of the species, in addition to possession of parasporal bodies. However, it is now apparent that *B. thuringiensis* isolates can be obtained from soil that has not been exposed to *B. thuringiensis*-derived insecticides and in which susceptible insects are not abundant. Moreover, many of these isolates are nontoxic for all insects tested. For example, Ohba and Aizawa (1986) isolated 189 cultures of *B. thuringiensis* from 136 soil samples collected from nonsericultural areas of Japan. The classification was based in part on possession of parasporal bodies (and not insect pathogenicity). According to Ohba et al. (1988), the majority of such *B. thuringiensis* isolates are nontoxic for a variety of insects.

De Lucca et al. (1981) conducted a similar survey of the presence of *B. thuringiensis* in soil in the USA. They found that *B. thuringiensis* represented between 0.5 and 0.005% of all *Bacillus* species isolated from the soil samples. Travers et al. (1987) screened soil samples collected from random locations in Montgomery County, MD, USA, for the presence of *B. thuringiensis*. It was found in almost all of the soil samples examined. Thus, it is obvious that *B. thuringiensis* is widespread in nature.

One might expect that epizootics caused by *B. thuringiensis* would be frequent, considering the widespread occurrence of the species in soil. However, epizootics are somewhat rare. Most epizootics have been limited to situations wherein the insect density is relatively high, providing better opportunity for establishing the disease within the population. In high density infestations of Douglas-fir tussock moth populations, for example, *B. thuringiensis* epizootics become a factor in reducing defoliation and eventual collapse of the population (Tunnock et al., 1974). Similarly, outbreaks of disease in insect populations have been reported in stored grain pests (Burges and Hurst, 1977; Vankova and Purrini, 1979) and in the European corn borer (Lynch et al., 1976). *B. thuringiensis* subsp. *israelensis,* which is a strain highly toxic to larvae of mosquitoes and some other hematophagous-insects (Klowden and Bulla, 1984; Tyrell et al., 1979), was first isolated from pond water in Israel wherein many diseased larvae were observed (Goldberg and Margalit, 1977; Margalit and Dean, 1985).

The artificial habitats are the locations where *B. thuringiensis* insecticides (usually a mixture of spores and crystals) are applied. Insecticides formulated with *B. thuringiensis* are currently being manufactured and used worldwide. Major producers in the USA, Europe, and the USSR make insecticides formulated with *B. thuringiensis*. Bulla et al. (1985) defined two groups of insecticides formulated with *B. thuringiensis*. Group I consists of products formulated with strains having toxicity against lepidopteran insects, whereas group II products are those with toxicities similar to *B. thuringiensis* subsp. *israelensis,* which are highly toxic to mosquitoes and certain other hematophagous dipteran larvae. With the discovery of strains such as subsp. *tenebrionis,* which are toxic to coleopteran larvae, a group III needs to be defined. Accordingly, *B. thuringiensis* may be applied as an insecticide on foliage, in soil, in water environments, and in food storage facilities (e.g., grain bins).

Isolation, Preservation, and Growth of Cultures

Isolation of *B. thuringiensis* from soil or other natural environments is greatly facilitated by use of selective techniques. Travers et al. (1987) took advantage of the observation that germination of spores in crystal-forming bacilli, including both *B. thuringiensis* and *B. sphaericus*, is inhibited by sodium acetate concentrations of approximately 0.25 M. Soil, which contained up to 10^9 bacteria/g, was inoculated into a nutrient medium that contained the sodium acetate. After a period of growth, the vegetative cells were eliminated by heat treatment and the remaining spores were isolated on a nutrient medium without acetate. The survivors from this treatment ranged from 20–96% *B. thuringiensis* and/or *B. sphaericus*. These two species are easily differentiated by observation of colonial and cellular morphology. Similarly, Saleh et al. (1969) exploited the observation that *B. thuringiensis* is relatively resistant to polymyxin B and penicillin G to isolate *B. thuringiensis* from soil.

Preservation of *B. thuringiensis* cultures is of special importance because of the common presence of multiple plasmids, some of which carry vital information; e.g., the crystal toxin gene (Faust et al., 1979; reference is not an exact match Gonzales et al., 1982). These plasmids may be lost during routine subculturing, and, therefore, crystal toxin production and, presumably, other plasmid-borne phenotypes may be simultaneously lost (Stahly et al., 1978). Investigators in R.E. Andrews' laboratory use three methods for culture preservation.

For long-term culture storage, cultures are grown until sporulation occurs (about 24 h) in

liquid GYS medium (Nickerson and Bulla, 1974). After >90% of the cells in the culture contain mature, phase-bright spores, the cells are harvested by centrifugation and resuspended in 20% skim milk. This material is then lyophilized by standard techniques (Gherna, 1981). For routine laboratory operations, several agar slant cultures are prepared at the same time by inoculation with the *B. thuringiensis* culture to be preserved. These are incubated at 30°C for 4 days to allow extensive sporulation and then stored at 4°C for up to 6 months. When a culture is required for an experiment it can be started from one of these stored slants, which are used only once after they are removed from cold storage. The slant methodology has certain disadvantages. The inoculum contains frequently variable amounts of spores and the culture outgrowth can be somewhat erratic. For synchronized sporulation of *B. thuringiensis*, another method is used. The culture is grown to midlogarithmic phase in liquid modified GYS medium ($A_{600} = 0.5$) and then diluted 1:50 in modified GYS medium containing 50% (vol/vol) glycerol. This material is divided into 100-μl portions and stored in sterile Eppendorf test tubes at −70°C. Viability remains high for up to 1 year.

B. thuringiensis is not particularly fastidious and can be routinely cultured on many complex media; e.g., Difco nutrient agar, LB agar (reference is not an exact match Maniates et al., 1982), and Difco brain heart infusion agar. Although *B. thuringiensis* is facultative, it grows best aerobically. For growth in liquid media, cultures are usually aerated by vigorous shaking of cultures in Ehrlenmeyer or Fernbach flasks. Those in the R.E. Andrews' laboratory use 100 ml of medium in 300 ml Ehrlenmeyer flasks and 1 l of medium in 2.8-l Fernbach flasks. The use of flasks with baffled bottoms is not necessary, but may increase growth rates by about 10% (R. E. Andrews, unpublished observation).

Much of the understanding of sporulation and crystal toxin formation is derived from the observation that *B. thuringiensis* can be grown and induced to sporulate in near synchrony. That is, as the cells begin to sporulate, >99% of the cells will be in the same morphological stage. Bechtel and Bulla (1976), for example, used a medium that contained glucose, yeast extract, citric acid, and salts (modified GYS) to study sporulation and crystal toxin with the electron microscope. In these studies, the parasporal crystals formed in synchrony and allowed a detailed understanding of the morphological events related to sporulation. Later Andrews et al. (1981, 1982, 1985) used these same culture methods to show that crystal antigen first appeared in the cells at a defined time during the sporulation process, and that its synthesis was induced by de novo synthesis of crystal toxin specific mRNA. Moreover, this medium can be used to produce a nearly pure suspension of spores and crystals that can readily be used to purify spores and/or crystals for further use (Tyrell et al., 1981). The methodology works well with all subspecies tested to date (R. E. Andrews, unpublished observations).

Investigators in R. E. Andrews' laboratory currently use the following method to achieve synchronous sporulation without excessively long incubation times. A small volume (usually about 5 μl) of the vegetative cell culture preserved in 50% glycerol at −70° is inoculated into 100 ml of YEG broth (Tyrell et al., 1981). The culture is incubated overnight (about 15 h) at 30°C with vigorous shaking. Some calibration of the starting inoculum is required to insure that the overnight culture does not reach stationary phase. A transfer is made (10% inoculum) to modified GYS medium, and the cells are grown to mid-exponential phase (A_{600}, about 0.5). This culture serves as inoculum for the final experimental culture. Inoculum (10%) is transferred into modified GYS medium. Growth begins immediately with a generation time of 50–60 min, the cells enter stationary phase (the beginning of sporulation) after about 4 h, and sporulation is complete by 12 h. The preliminary transfers result in selection for rapidly growing cells, thus insuring development of physiological and morphological synchrony during sporulation.

Growth requirements for *B. thuringiensis* are relatively simple. Nickerson and Bulla (1974) and Kuznetsov and Khovrychev (1984) described growth and sporulation of several *B. thuringiensis* strains in synthetic media. In addition to basal salts these media, which were similar in composition, contained glucose and glutamate, although some strains required aspartate, citrate, alanine, and/or nicotinic acid. Growth is slower than in complex media, with doubling times often in the range of 3–4 h, but such media should facilitate nutritional studies and selection of auxotrophic mutants.

The conditions used for commercial production of *B. thuringiensis* differ somewhat from those used in the laboratory. Fermentation media usually include unrefined substrates such as corn steep solids, molasses, corn starch, cotton seed flour, fish meal, hydrolyzed casein, groundnut cake, and soybean cake. Although sporulation is probably a prerequisite to crystal toxin, the goal of such fermentations is to optimize the production of crystal toxin rather than to maximize the formation of spores. Typically, fermentation begins with inoculation of a 15-l vessel from a seed culture. This 15-l culture is then used to inoculate larger vessels, and typical final fer-

mentation volumes as large as 30,000 to 100,000 l are common (Andrews et al., 1987).

Identification

MORPHOLOGICAL CHARACTERISTICS. *Bacillus thuringiensis* cells are Gram-positive, spore-forming, and rod-shaped. The cells are straight rods that are typically 1.0–1.2 by 3–5 μm in size when grown in standard liquid media. Terminal to subterminal ellipsoidal spores are formed in sporangia that are not swollen. Probably the most characteristic distinguishing feature of *B. thuringiensis* is the presence of a parasporal crystal that forms adjacent to the spore, outside the exosporium during endospore formation. The presence of the parasporal crystal in cells and the production of insecticidal activity remain the best criteria available for differentiation of *B. thuringiensis* from the closely related species, *B. cereus* (Andrews et al., 1987; Baumann et al., 1984; Claus and Berkeley, 1986).

There is an interesting correlation between the spectrum of toxic action of a given strain and the shape of the crystal it produces. This is discussed in more detail elsewhere in this chapter. For the purpose of this discussion it is important to note, however, that the shape of the crystalline toxin can provide some important clues to the identity of the *B. thuringiensis* isolate in question. Subspecies *kurstaki,* for example, produces a single bipyrimidal crystal, whereas subsp. *israelensis* produces multiple, plemorphic, and globular crystals. If the task at hand is to differentiate between these two subspecies, the observation of crystals by use of a phase contrast microscope will provide meaningful information.

PHYSIOLOGICAL CHARACTERISTICS. Identification of *B. thuringiensis* by physiological characteristics is difficult. Aside from the presence of the crystal toxin, phenotypic characteristics to distinguish between *B. thuringiensis* and *B. cereus* are few. Claus and Berkeley (1986) compared approximately 40 phenotypic characteristics among the bacilli. These two species could not be differentiated by any of these physiological criteria. Baumann et al. (1984) and Lynch and Baumann (1985) examined 137 isolates of *B. thuringiensis* and 35 strains of *B. cereus* for the presence or absence of 99 phenotypic characteristics. Numerical analysis of the data showed that the various subspecies of *B. thuringiensis* (based on flagellar H antigen type) and *B. cereus* did not form two distinct clusters. On the contrary, *B. thuringiensis* and *B. cereus* strains were randomly dispersed throughout the dendrogram. Thus, although identification of an isolate as belonging to the *B. cereus-B. thuringiensis* group can be accomplished by using physiological criteria, other methods are required to distinguish between the two species. Also, a determination of physiological characteristics is of no value in differentiating between the *B. thuringiensis* subspecies.

IMMUNOLOGICAL CHARACTERISTICS. Immunological methods have also been used to identify *B. thuringiensis*. In addition, the basis for the subspecies classification of an isolate is largely based on antigen identification (de Barjac and Bonnefoi, 1962, 1973). Two antigenic targets have been used for immunological identification of *B. thuringiensis*, the flagellar antigens and the crystal toxin protein.

By immunologically analyzing strains for flagellar H antigens, more than 20 subspecies of *B. thuringiensis* have been identified (de Barjac and Bonnefoi, 1962, 1973; Krywienczyk et al., 1978). Although the major criterion for classification of an isolate as *B. thuringiensis* is the presence or absence of the crystal toxin, the use of H antigens has distinct advantages for the identification of subspecies. There is extensive evidence that the crystal toxin gene is frequently located on self transmissible plasmids (Battisti et al., 1985; Gonzales et al., 1982; Green et al., 1989; Klier et al., 1983; Ruhfel et al., 1984; Stahly et al., 1978). Moreover, the crystal toxin gene in many *B. thuringiensis* isolates has been shown to be surrounded by transposon-like DNA sequences (Bourgouin et al., 1988; Lereclus et al., 1984; Lereclus et al., 1986; Mahillon and Lereclus, 1988; Mahillon and Seurinck, 1988; Mahillon et al., 1985, 1987) and, therefore, may be transferable between strains. Thus, because the crystal toxin type produced by a *B. thuringiensis* isolate is probably a relatively inconstant characteristic, use of a more stable antigen as a target for identification is of greater utility. Presumably the flagellar antigen would be of chromosomal origin and would therefore exhibit such stability.

Despite their comparatively unstable nature, crystal toxin antigens have been used for identification of *B. thuringiensis* subspecies. As taxonomic tools, the limitations of these methods have already been described (Krywienczyk, 1977; Krywienczyk et al., 1981). There are, however, some important applications for the use of these antigens; the observation that the crystal toxin presence is intimately correlated with insecticidal activity has been discussed previously. Thus, immunological determination of crystal toxin presence is a useful method for estimating toxic activity of insecticidal preparations. Rocket immune electrophoresis, for example, has been used to determine the toxin content in cultures of *B. thuringiensis* during growth and

sporulation (Andrews et al., 1980, 1981, 1985). This method is rapid and simple, and it reliably estimates the toxic activity of cultures (Andrews et al., 1980). Immunological methods can also be used to quantify crystal toxin in the environment, and they are useful, therefore, for determination of residual insecticidal activity after pesticide application. Enzyme-linked-immunosorbent assay (ELISA), for example, can be used to determine crystal antigen with reasonable sensitivity even under field conditions (Wie et al., 1982, 1984).

In addition to quantification of insecticidal activity, there is another important use for immunological measurement of crystal toxin antigens. Immunological methods provide qualitative information about the crystal toxin. Wie et al. (1982) prepared antibody directed against the crystal toxin of an isolate of subsp. *kurstaki,* and then used heterologous crystal toxin proteins from several other subspecies to inhibit the homologous reaction in ELISAs. Of the five heterologous crystal types examined, four were toxic to lepidopteran larvae, and all four of these were highly inhibitory to the toxin antitoxin homologous reaction. As discussed below, DNA sequence data show that the toxin genes of lepidopteran-toxic strains of *B. thuringiensis* exhibit considerable homology. Tyrell et al. (1981) prepared sera against several crystal toxins from different subspecies and, by using Ouchterlony double diffusion assays, were unable to demonstrate cross-reactivity between the lepidopteran-toxic crystal antisera and the subsp. *israelensis* crystal toxin antigens. Interestingly, although no cross-reactivity was demonstrated with the Ouchterlony assays, Wie et al. (1982) found a low but significant (about 10%) inhibition of the subsp. *kurstaki* homologous reaction when the subsp. *israelensis* crystal protein was used in ELISA studies. The significance of this inhibition did not become clear until DNA sequencing studies revealed that these two toxins shared some similarity (Thorne et al., 1986). Therefore, immunological techniques employing crystal toxin antigens may have an important role in the regulatory process regarding pesticide registration. Under U.S. law, the Office of Pesticide Regulation of the Environmental Protection Agency has a responsibility to ensure that the toxin in a pesticide is the same as that contained therein at the time of the initial registration. Given the genetic exchange capacity of *B. thuringiensis*, these methods allow the registrant to characterize, in a standard manner, the active ingredient of their product, and to ensure that the current production strain expresses the same toxins and toxicity as when it was first registered.

GENETIC CHARACTERISTICS. Characterization of an isolate's DNA content is an important method for identifying *Bacillus thuringiensis*. The DNAs from *B. thuringiensis*, *B. anthracis*, and *B. cereus* are highly homologous, exhibiting >90% homology (Kaneko et al., 1978). Even though these other two species are common in soil, it should still be possible to use DNA probes to identify an isolate as *B. thuringiensis* by using a crystal toxin gene as a probe to detect homologous DNA target sequences in the test strain (Prefontaine et al., 1987). Use of such a DNA probe would obviate the need to detect the gene product, crystal toxin. As previously described, the major criterion for classification of an isolate as *B. thuringiensis* is the presence of crystal toxin. It is possible, however, that a crystal toxin gene may be present but not expressed. A mutation in the toxin gene could prevent expression. Klier and Lecadet (1976) first suggested and then Brown and Whiteley (1988) confirmed that a unique form of RNA polymerase is required for transcription of the crystal toxin gene in *B. thuringiensis*. Subsequently, Adams et al. (1989) have shown that a 20-kDa protein is required for expression of the crystal toxin gene. Mutations that effect expression of genes encoding one of these required components would create a strain that is unable to produce crystal toxin but contains an intact crystal toxin gene. It is unclear at present whether such mutants occur in nature, but their presence would certainly further confuse the taxonomic data.

Plasmid analysis can be used to identify specific isolates within the species *B. thuringiensis*. Most isolates of *B. thuringiensis* contain multiple plasmids ranging from as small as 1–2 kb in size to over 100 kb. Moreover, many isolates have unique plasmid size profiles that can be used in strain determination (Carlton and Gonzalez, 1985; Gonzales et al., 1982; Kronstad et al., 1983; Mahillon et al., 1988; Stahly et al., 1978; Stepanova and Azizbekian, 1987). Because of the potential loss of plasmids during extended culturing (Dean, 1984; Stahly et al., 1978) this method may be of somewhat limited utility as well.

Ecophysiology

Most evidence seems to indicate that the disease symptoms caused by *B. thuringiensis* are almost entirely due to the crystal toxin, often referred to as delta-endotoxin (Andrews et al., 1980; Fast, 1977). Andrews et al., (1987) have argued that the term "endotoxin" is inappropriate, because this term is commonly used to refer to toxic lipopolysaccharide components of cell walls from Gram-negative cells. (The toxin of *B. thuringiensis* shares some striking similarities to the

toxins of *Clostridium botulinum* and *Clostridium perfringens*; [Andrews and Bulla, 1981].) Spores alone are much less effective than either crystals alone or a mixture of the two. The relative ineffectiveness of spores alone is apparent in laboratory infectivity studies. Also, under field conditions, reinfection after application of insecticides is difficult to demonstrate (Couch and Ignoffo, 1981). In contrast, some evidence supports the view that other factors produced by *B. thuringiensis* are important in pathogenesis. As discussed in more detail below, β-exotoxin and certain proteases are produced by growing cells and are clearly active against insect systems. Some insects probably require viable spores for pathogenicity (Bulla et al., 1985). Finally, when an insect larva dies, the dead insect carcass usually contains relatively large quantities of spores and crystals (Aly, 1985; Aly et al., 1985; Prasertphon et al., 1974), indicating that septicemia typically follows the toxemia.

The observations that epizootics caused by *B. thuringiensis* occur relatively infrequently in nature, that the organism can be readily isolated from soils, that the crystal toxin is a normal component of the spore coat (Aronson et al., 1982; Somerville et al., 1968; Tyrell et al., 1981), and that *B. thuringiensis* is a relatively close relative of the common soil bacterium *B. cereus* (Andrews et al., 1987) imply a model for the microbe's ecology. This evidence suggests that the primary habitat of *B. thuringiensis* is soil. Somewhere over the course of evolution a common parent gained, either by mutation or genetic exchange, a spore coat protein that was toxic to insect larvae. By overproduction of this protein, the organism was able to kill an insect host and use the nutrients from that host in a saprophytic mode. This model would imply that the normal habitat for *B. thuringiensis* is soil, but that as the opportunity presents itself, the organism is able to use the insect as a temporary niche.

THE CRYSTAL TOXIN. As previously stated, *B. thuringiensis* is probably best known as a pathogen of insects. In nature, the disease is restricted to insect larvae; in the laboratory, toxicity to some adult insects of crystal protein has been reported when administered orally and/or rectally (Klowden and Bulla, 1984; Klowden et al., 1985). Moreover, the development stage of the larvae has a profound effect on its susceptibility to the toxin. Generally, younger larvae are more susceptible than older larvae (Andrews et al., 1987; Rasnitsyn et al., 1988). Because the route of entry of *B. thuringiensis* is through the oral cavity, ingestion of the toxin is mandatory, which requires insect feeding activity (Bulla et al., 1985).

Insects susceptible to the *B. thuringiensis* crystal toxin generally have alkaline midguts (pH ranges typically 10–12). At such pH the crystals solubilize and for some toxin types further activation may follow. Within the first minutes, a paralysis of the midgut and mouthparts ensues; these symptoms are accompanied by a drop in the pH of the insect gut and an increase in the hemolymph pH. The histological effects of the crystal toxin seem to be confined to the larval midgut epithelium and peritrophic membrane. Scanning electron micrographs of the larvae of *Manduca sexta* show that as soon as 1 h after oral administration of the toxin the microvilli in the midgut become shrunken, and after 4 h extensive midgut damage is observed. These histological changes are accompanied by a series of anomalies in the larvae's physiology. There is a severe restriction of potassium transport that is believed to be responsible for the maintenance of the high midgut pH. Active transport of potassium is inhibited about 78% within 10 min after ingestion, and, after several hours, all active transport ceases. Shortly after ingestion, the insect's peritrophic membrane becomes more permeable to particulate matter (Adang and Spence, 1983; Andrews et al., 1987; Gupta et al., 1985).

The mode of action of the crystal toxin has been reviewed (Andrews et al., 1987; Höfte and Whiteley, 1989). There is a marked similarity between the pathology of insects that have ingested the *B. thuringiensis* crystal toxin and that of humans suffering from cholera. Because of this similarity, much work has focused on the effect of the toxin on adenyl cyclase and intracellular cyclic AMP (cAMP) levels in diseased insects and in cultured cells that have been treated with toxin preparations. Knowles and Farndale (1988) found that treatment of cultured cabbage moth cells with *B. thuringiensis* toxin induced elevated cAMP levels and adenyl cyclase activity. However, when these cells were treated with the bee-venom toxin melittin, which also lyses the cells, they found similar effects. Therefore, the authors reasoned that the effect was secondary and was not directly related to the toxin's activity but rather consisted of a cellular response to lytic action.

Some evidence is beginning to accumulate relating to the mode of action of the toxin and its target or binding site. Knowles and Ellar (1987), for example, showed that insect cells cultured in the presence of ^{51}Cr, ^{86}Rb, and ^{3}H-uridine rapidly released those small molecules when treated with *B. thuringiensis* toxins that came from different subspecies. The receptor molecule may lie in the brush border membrane of epithelial cells. Sacchi et al. (1986) demonstrated that in midgut cells of the cabbage butterfly *Pieris brassicae,* K+-gradient-dependent

amino acid transport across the brush border membrane was inhibited by the *B. thuringiensis* toxin. Moreover, Hofmann et al. (1988a) demonstrated the presence of high affinity binding sites for the toxin of *B. thuringiensis* subsp. *thuringiensis* on the brush border membrane of midgut epithelial cells from *P. brassicae.* Several lines of evidence suggested that these were the natural binding sites for the *B. thuringiensis* toxin. I[125]-labelled toxin readily bound to the target cells, whereas toxin binding to nontarget cells (rat small intestine epithelial cells) was observed with much lower affinity (Hofmann et al, 1988a). I[127]-labelled, or unlabelled toxin competitively inhibited binding to the target cells but did not inhibit binding to the nontarget cells. The toxin from *B. thuringiensis* subsp. *thuringiensis,* although highly toxic for *P. brassicae,* is not toxic for larvae of the tobacco hornworm *Manduca sexta.* The toxin did not bind significantly to brush border membrane vesicles prepared from the larval midgut of *M. sexta,* a further indication that the binding to *P. brassicae* cells is specific (Hofmann et al., 1988b). Finally, Knowles et al. (1984) examined the effect of toxin on *Choristoneura fumiferana* CF1 cells in vitro. Preincubation of the toxin with N-acetylgalactosamine and N-acetylneuraminic acid specifically inhibited lysis of the target cells, and because N-acetylneuraminic acid has not been known to occur in insects, it was concluded that the toxin may recognize a specific plasma membrane glycoconjugate receptor with a terminal N-acetylgalactosamine residue. Considered togther these results suggest that the crystal toxin of many strains of *B. thuringiensis* binds to a glycoconjugate receptor on the brush border membrane of the insect midgut epithelium and then induces pore formation, resulting in leakage of the cells, followed by lysis.

OTHER PATHOGENIC FACTORS. Because of the importance of the crystal toxin to the activity of *Bacillus thuringiensis* insecticides, there has been a focus in research on this agent as a cause of insect pathology. It must be recognized, however, that other pathogenic factors are produced by certain *B. thuringiensis* isolates. Because of the nature of these factors, it is difficult to understand how they would function in ways other than to aid in an invasive propagation of *B. thuringiensis* cells in the insect.

One such factor is the so called β-exotoxin. The β-exotoxin, or fly factor, produced by some strains of *B. thuringiensis* is a heat stable nucleotide analog that is a potent inhibitor of RNA polymerase. This toxin is produced by β-exotoxin-positive cells during the stationary phase of growth and is broadly toxic to a variety of insects, both larvae and adults. Fly factor is an inhibitor of insect, mammalian, and bacterial RNA polymerases, and this activity is thought to be its mode of action. The heat stable properties and the toxic activity to *Musca domestica,* the house fly, are used to identify β-exotoxin activity in extracts (Beebee et al., 1972; Iandolo et al., 1976; Johnson, 1976, 1978; Johnson et al., 1975; Kim et al., 1972). Because of its toxicity and the possibility that it may be mutagenic, β-exotoxin-producing strains are currently banned in insecticidal formulations, but consideration has been given to the use of this factor itself as an insecticide (Bulla et al., 1985). As a final note, it is possible that the primary function of β-exotoxin is not as a pathogenic factor. Several kinds of observations lead to this conclusion. 1) β-Exotoxin is found primarily in spores, not in vegetative cells (Johnson, 1976) as would be expected for an invasive factor. 2) The RNA polymerases from sporulating cells of *B. thuringiensis* are up to 50% less sensitive to β-exotoxin than are those from vegetative cells, *E. coli*, or insects (Johnson, 1978). 3) Finally, there is no evidence to suggest that β-exotoxin-positive cultures are more pathogenic than are β-exotoxin-negative strains.

This evidence might lead to an alternative explanation for the presence of the toxic factor. Perhaps β-exotoxin is a normal regulatory factor important for control of sporulation in *B. thuringiensis*; the normal function might be to suppress expression of vegetative genes during sporulation. Under normal conditions, β-exotoxin is present at levels below normal detection in the so-called negative isolates. Strains that are termed positive simply have evolved a mechanism to overproduce the toxin, thus providing them a slight selective advantage in nature. Clearly, a better understanding of the role and occurrence of the β-exotoxin in *B. thuringiensis* is required to answer this question.

Many early investigators looked for specific immune systems analogous to the antibody response elicited by vertebrate animals when attacked by a bacterial invader. No specific agglutinating activity has been observed in insects. Insects do react with a defensive response during an intrusion by a bacterial invader, but the reaction is non-specific. The cecropins and attacins are two such classes of defensive proteins. These proteins, analogs of which have been identified in a wide variety of insects, are thought to function to lyse bacterial cells; the action is non-specific in that proteins induced by one bacterial species, for example, *E. coli* lyse cells from another species, *B. thuringiensis* (Hultmark et al., 1982, 1983; Hurlbert et al., 1985; Kaaya et al., 1987; Spies et al., 1986).

The finding that *B. thuringiensis* has been observed to produce a protease capable of spe-

cifically inactivating cecropins and attacins is particularly intriguing. This protein, inhibitor A, has been shown to attack and selectively destroy cecropins and attacins and thus to reduce the insect defense response. The protease is specific; although it does not seem to recognize a specific sequence, it attacks an open hydrophobic region near the C-terminus of the cecropin, and it does not attack globular proteins (Dalhammar and Steiner, 1984). The similarity between this pathogenic factor and an analogous factor produced by *Pseudomonas* species involved in infections in cystic fibrosis patients is striking. In the case of cystic fibrosis, it has been shown that several *Pseudomonas* isolates produce proteases that specifically degrade certain immunoglobins (Fick et al., 1984; Holder and Wheeler, 1984).

CRYSTAL TOXIN BIOCHEMISTRY. Despite the other pathogenic factors produced by *Bacillus thuringiensis*, by far the most research effort has been placed on the crystalline toxin, and this agent is therefore the best understood. There is a striking correlation between the shape of the parasporal crystal and the spectrum of toxicity it displays. The lepidopteran-toxic crystals are bipyrimidal in shape, the dipteran toxic crystals are pleomorphic, and coleopteran-toxic crystals are rectangular and flat. If toxicity truly resides in a discrete polypeptide subunit and if the individual polypeptide subunits have different ranges of toxicity to insects, then the molecular details of their structures must differ in significant ways and, hence, their crystals should have different topographical shapes. Therefore, it is possible that significant information about specificity of the proteins produced by a given isolate may be derived from a study of the crystal configuration.

Immunological comparison of the crystal toxin antigens has already been discussed. Antisera against crystals from several strains of pathotype I and from subsp. *israelensis* (pathotype II) were prepared by Tyrell et al. (1981). In Ouchterlony double diffusion assays, cross-reacting epitopes were not observed between pathotype I strains and the pathotype II strain, whereas an evidently homologous reaction was observed among the pathotype I strains. Using the more sensitive ELISA technique, however, differences among the pathotype I strains were noted and some similarity between these and the subsp. *israelensis* crystal proteins was apparent (Wie et al., 1982). Interestingly, crystal proteins from subsp. *tenebrionis* (pathotype III) did not serological cross-react with proteins from crystals of the other two pathotypes (Krieg et al., 1987b).

The crystals from all three pathotypes share some common properties. The most obvious of these is that they are all protein. Moreover, despite the antigenic diversity, the polypeptides contained in the crystals tend to have some common size ranges. For example, when crystal proteins from pathotypes I and II are separated on sodium dodecyl sulfate (SDS) polyacrylamide gels, major bands appear in the molecular weight (mol wt) range of 120,000–140,000 and a second band or group of bands in the mol wt range of 60,000–70,000. In addition, pathotype II crystals contain a third polypeptide (mol wt range of 23,000–30,000). Pathotype III crystals contain only proteins in the middle range. Under conditions of neutral and acid pH, the crystals are insoluble; in fact, the insolubility of the proteins and their tendency to re-form crystals and precipitate under such conditions remains a major problem in the laboratory. As previously discussed, insects sensitive to the crystal toxin of *B. thuringiensis* share the common property of having alkaline midguts. Not surprisingly, the crystals from all three pathotypes become soluble under alkaline conditions and in all cases the proteins retain toxicity. The crystal proteins from subsp. *israelensis* lose a substantial portion of their toxicity in insect bioassays when they are solubilized. However, this has been shown to result from a problem in the insect assay procedure rather than from damage to the protein itself, because when the solubilized crystal proteins are adsorbed onto latex beads, the proteins regain most of their toxicity (Andrews et al., 1981; Bulla et al., 1981; Calabrese et al., 1980; Huber et al., 1981; Insell and Fitz-James, 1985; Lilley et al., 1980; Schnell et al., 1984; Tyrell et al., 1979).

PATHOTYPE I CRYSTAL PROTEINS. Crystal proteins from pathotype I isolates share a number of common features. The most obvious of these has already been pointed out; namely, they usually share a common crystal shape and contain proteins in a common size range (130,000–140,000). They are antigenically cross-reactive. The protein subunits are protoxin molecules that are converted to a toxic form after ingestion by a susceptible insect. Upon ingestion, the crystal becomes soluble in the insect midgut and is then activated, via proteolytic cleavage, to a toxin (mol wt = 68,000). The evidence suggests that the proteases responsible for toxin activation are insect-derived. Crystal proteins from subsp. *kurstaki* strain HD1, for example, are composed of repeating subunits of mol wt = 135,000 (Bulla et al., 1981). When the crystals are solubilized at pH 12, dialyzed against a pH 7.5 buffer, and allowed to stand at room temperature for several days, there is a conversion of some of the material to a smaller molecule (mol wt = 68,000) that is thought to be the toxin (Bulla et al., 1979). When these data appeared in the literature there were several items of controversy regarding this

model. One area of concern was that the yield of toxic product was low relative to the quantity of starting crystal protein used, leading to some speculation that this was an artifact. Andrews et al. (1985) showed that under appropriate conditions the conversion of protoxin to toxin could be done in vitro using commercially available trypsin and that this treatment did not reduce the toxicity significantly. In these studies the soluble proteins from subsp. *kurstaki* were approximately four fold more toxic than were whole crystals. When these proteins were dialyzed against a dilute carbonate buffer and treated with limiting quantities of trypsin, nearly all the toxic activity (>90%) in the soluble crystal preparation was recovered, but the protein in the solution was now almost exclusively of a mol wt = 68,000. This means that the molar toxicity of the preparation remained constant, whereas the LC_{50} (concentration that is lethal to 50% of the treated insects) of the proteins had approximately doubled. Similar conversions were demonstrated using insect gut-derived proteases, confirming that enzymes from the larval midgut probably were responsible for the conversion in vivo (Tojo and Aizawa, 1983).

These data left one observation unexplained; crystals purified from all pathotype I strains examined before 1985 contained a molecule of approximately 68,000 mol wt (Tyrell et al., 1981). Since purified toxin comigrated with this smaller molecule, there was controversy over its origin. A better understanding of this problem came with the recognition that a strain of subsp. *kurstaki* (HD251) evidently did not contain, or contained very little, of the 68,000 mol wt protein in its crystals. Upon further examination, strain HD251 was shown to produce greatly reduced levels of intracellular proteases, but produced normal levels of toxicity. Subsequently, it was shown that the small quantity of 68,000 mol wt protein found in crystals of most pathotype I strains probably resulted from conversion of protoxin to toxin by intracellular proteases produced by *Bacillus thuringiensis* during the sporulation process (Andrews et al., 1985; Bibilos and Andrews, 1988).

Genetic observations confirmed conclusions derived from protein chemistry. From 1981 to 1989 at least 49 reports of cloning and/or sequencing of *B. thuringiensis* crystal toxin genes appeared in the literature (Table 1), and 30 of these reports were of genes encoding proteins with toxicity to Lepidoptera. Only two of these reports were of genes encoding proteins in the size range of 60,000–70,000 mol wt, whereas all of the others were of genes encoding proteins in the size range of 120,000–140,000 mol wt. Moreover, because both of the smaller proteins show a toxicity to both lepidopteran and dipteran larvae, it is unclear that these are true pathotype I toxins. Therefore, the DNA cloning and sequence data confirm that the crystal toxin subunit in pathotype I crystals are usually, if not always, composed of proteins of mol wt 120,000–140,000. DNA sequencing studies also confirmed the protoxin to toxin conversion hypothesis. Data from a number of laboratories showed that the toxin molecule was derived from the amino-terminal portion of the protoxin (Schnepf et al., 1985; Wabiko et al., 1985).

Crystals from some isolates contain multiple toxin proteins, each with a distinct host range of toxicity, and the total activity spectrum of the crystal represents a summation of the individual toxic spectra. For example, the crystals from subsp. *aizawai* contain at least two different toxin proteins, one of which is specific in its activity for *Pieris brassicae* and the other for *Spodoptera littoralis,* both of which are lepidopterans (Lecadet et al., 1988). The two types of subsp. *aizawai* genes have been cloned and their distinct toxicities confirmed (Sanchis et al., 1988). Similar data were provided by Knowles and Ellar (1988), who observed that subsp. *aizawai* contained two proteins, one of which was toxic to *Choristoneura fumiferana* and the other to *S. frugiperda.* Multiple genes have been cloned from subsp. *entomocidus* (Visser et al., 1988), subsp. *morrisoni* (Granum et al., 1988), subsp. *thuringiensis* (Brizzard and Whiteley, 1988), and subsp. *kurstaki* (Widner and Whiteley, 1989).

There may be some clues in the literature regarding the significance of these different genes. In a report that is both interesting and alarming, McGaughey (1985) observed resistance to the *B. thuringiensis* toxin in an insect population. While trying to use *B. thuringiensis* to control *Plodia interpunctella* in grain bins, he observed that in some cases the populations were suppressed, whereas in others a similar concentration of insecticide did not achieve effective results. Upon further examination, it was observed that in as few as 15 generations of continual selection, the LC_{50} of the toxin increased nearly 100-fold. That a population can become resistant in such a short time raises obvious concerns about the use of *B. thuringiensis* insecticides. Interestingly, however, in later studies it was noted that insects were selectively resistant to certain toxin types while still sensitive to others (McGaughey and Johnson, 1987). The presence of resistance in a population may explain the presence of multiple toxin genes within a single isolate of *B. thuringiensis;* multiple genes may be a mechanism for overcoming the development of resistance. At the present time, resistance has only been observed in *P. interpunctella,* and it is unclear how widespread or universal this resistance will become.

Table 1. Survey of reported *B. thuringiensis* crystal protein genes cloned between 1981 and 1989. Adapted from Hurley (1989).

Source of the cloned gene (subspecies and/or strain)	Type of report (cloning and/or sequence)	Insect specificity of gene	Molecular weight of protein coded by gene	Reference

PATHOTYPE II CRYSTAL PROTEINS. As previously indicated, one unique feature of the pathotype II isolates is that their crystals contain a polypeptide smaller than that observed in the other two pathotypes. Moreover, this smaller protein (mol wt = 23,000) is clearly the most abundant of the proteins in the crystal toxin. Also, the various polypeptides found in crystals of subsp. *israelensis* did not antigenically cross-react with each other, unlike the situation with pathotype I strains. Specifically, the proteins in the 120,000–140,000 mol wt range react with antibody prepared against the proteins in the 60,000–70,000 mol wt range, but the 23,000 mol wt proteins do not; nor do the larger proteins react with antibody prepared against the 23,000 mol wt protein (Pfannenstiel et al., 1986; Tyrell et al., 1981).

Shortly after the initial observations regarding the polypeptide profiles in subsp. *israelensis,* a potent and highly nonspecific cytolytic activity was observed in these crystals. A number of investigators quickly purified the activity and ascribed it to the 23,000 mol wt protein (Armstrong et al., 1985; Chilcott and Ellar, 1988; Davidson and Yamamoto, 1984; Ibara and Federici, 1986; Insell and Fitz-James, 1985). Many of these investigators observed both cytolytic and toxic activity associated with this protein and identified it as the toxin molecule. The protein is active on cells from insects of several orders, on mammalian cells, and even on some bacterial cells. From a functional standpoint it was difficult to understand how such a nonspecific activity when tested on cells in vitro could have such a specific effect in vivo. Moreover, the toxicity of the purified cytolysin was approximately 100- to 1000-fold less than that of solubilized proteins of whole crystals. Accordingly, Hurley et al. (1985) first demonstrated that the activities could be separated, and then purified the 23,000 and 68,000 mol wt polypeptides (Hurley et al., 1987). The smaller protein, when purified, was highly cytolytic, whereas the larger protein was toxic to mosquito larvae (1000 times more toxic than the cytolysin). In addition to observing toxic activity in the 68,000 mol wt protein, high levels of toxicity were observed in the larger proteins as well. Hurley et al. (1987) attributed the disagreement between their data and that of the others to two factors: 1) In one report, a 65,000 mol wt molecule was purified and shown to be relatively nontoxic (Ibarra and Federici, 1986). However, these investigators used SDS to solubilize the toxin preparation; and at least with the lepidopteran toxins, this had previously been shown to eliminate activity (Huber et al., 1981). 2) When in purified form, the toxin was unstable and readily degraded to smaller nontoxic forms. It was unclear whether this instability was intrinsic or caused by contam-

inating protease. Proteases associated with the crystal toxin of subsp. *israelensis* had already been reported (Chilcott et al., 1983). Although evidence from protein chemistry was becoming convincing, the ultimate proof would come from gene cloning experiments.

Bourgouin et al. (1986) constructed a library of *B. thuringiensis* subsp. *israelensis* plasmid DNA in an *E. coli* plasmid vector and identified three genes coding for proteins of 26, 73, and 135 kDa, respectively, located on a single 75-kb plasmid. Interestingly, the 73 and 135 kDa proteins produced from the cloned genes were both toxic, and the 73-kDa protein appeared to be a truncated version of the larger gene. The 23-kDa protein-encoding gene did not appear related to the other two, and the protein produced from the cloned gene was not toxic but was highly cytolytic. The surveyed gene cloning literature seems to support their conclusions. Of the 49 reports of cloned and/or sequenced crystal toxin genes from *B. thuringiensis* in the literature, five are of cytolysin genes, and all five genes encode proteins having molecular weights in the range of 26,000–28,000 (Table 1). There are 16 reports of dipteran toxic protein genes (including lepidopteran and dipteran toxic protein genes) from *B. thuringiensis* in the surveyed literature and of these four genes code for proteins in the 60–70 kDa range, whereas 11 code for proteins in the 120–140 kDa range, and 1 has no reported molecular weight (Table 1).

Since the isolation of subsp. *israelensis* there have been other isolations of pathotype II *B. thuringiensis* strains reported. These evidently belong to other subspecies based on their serotype and probably have proteins in their crystals similar to those in subsp. *israelensis* (Gill et al., 1987; Padua et al., 1980). Although the cytolysin is not the primary toxin, it is not without function. Evidence suggests that the cytolysin may act synergistically with the toxin (Hurley et al., 1987; Wu and Chang, 1985). There are evidently two forms of the toxin gene; however, their role is not understood.

PATHOTYPE III CRYSTAL PROTEINS. Owing to the relatively recent isolation of pathotype III strains, there is far less information regarding these crystal toxin proteins. It is interesting to note, however, that most of the controversy regarding the crystal proteins from the other two pathotypes was resolved not by protein chemistry but by gene cloning technology. Because pathotype III strains were isolated after gene cloning technology became available, it is not surprising that there has been much less controversy regarding the content of these crystals. The prototype strain for pathotype III is subsp. *tenebrionis.* The crystals from subsp. *tenebrionis*

appear to contain two polypeptides of mol wt 68,000 and 72,000 (Krieg et al., 1987b). Five of the 49 cloned and/or sequenced genes reported in Table 1 are for pathotype III crystal proteins, and the data are in remarkable agreement with the protein chemistry data. The literature regarding pathotype III strains is not without controversy, however. There has been a report of a second subspecies of pathotype III, termed subsp. *san diego* (Ferro and Gelernter, 1989; Herrnstadt et al., 1986) but there are claims that this strain is identical to subsp. *tenebrionis* (Krieg et al., 1987a).

CRYSTAL TOXIN SYNTHESIS. There is substantial literature to support, at least with most subspecies of *B. thuringiensis*, that the production of crystal toxin is linked to sporulation. Several lines of evidence support this conclusion. First, the parasporal crystals appear in the cells in close proximity to the spore, and the time of their appearance when viewed by phase contrast and electron microscopy closely coincides with spore formation (Bechtel and Bulla, 1976). Fig. 1 shows a diagram of the relationship between sporulation and crystal toxin production in subsp. *kurstaki*. Moreover, crystal toxin antigen accumulates in the cells only between 4 and 6 h after the onset of sporulation (Andrews et al., 1981).

The synthesis of crystal toxin is evidently controlled at the level of transcription. Synthesis of mRNA specific for crystal toxin, as measured by in vitro translation (Andrews et al., 1982) and Northern blotting (Kronstad and Whiteley, 1984), correlates with the accumulation of crystal toxin antigen in sporulating cells. Moreover, there is evidence that formation of mRNA specific for crystal toxin requires a unique form of RNA polymerase (Brown and Whiteley, 1988). In subsp. *israelensis* the presence of a 27-kDa protein is required (Adams et al., 1989). There is a notable exception to the association between crystal toxin production and sporulation, however. In subsp. *tenebrionis,* it appears that crystal toxin proteins are synthesized in vegetative cells (Sekar, 1988).

Genetics

The most extensive studies on the genetics of *B. thuringiensis* have focused on cloning and characterization of the crystal toxin genes. This information was presented in the previous section to aid in understanding the nature of the toxins and will not be reiterated in this section.

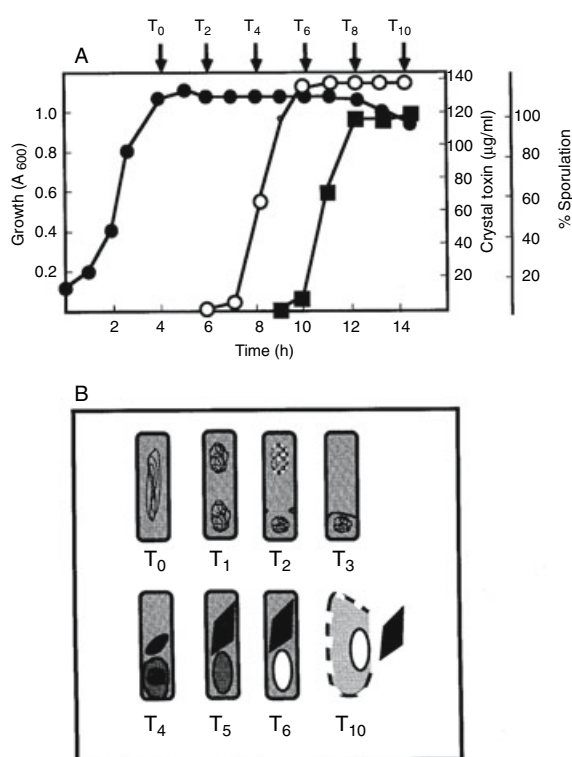
PLASMID BIOLOGY. *B. thuringiensis* isolates typically contain numerous plasmids, ranging in size from 2 to >200 kb. A given strain may carry up to 17 plasmids of distinct sizes (Gonzalez et al.,


Fig. 1. Growth, sporulation, and crystal toxin formation in *B. thuringiensis*. (A) A typical growth curve of *B. thuringiensis* subsp. *kurstaki*. The solid circles represent growth, the open circles show the formation of crystal toxin antigen, and the closed squares show the percentage of cells that contain complete, phase-light spores. (B) An artist's conception of growth, sporulation, and crystal toxin production in *B. thuringiensis* subsp. *kurstaki*. The data are based on electron micrographs published by Bechtel and Bulla (1975) and on phase-contrast microscopic examination of the sporulating cultures shown in A. The cells were grown in liquid GYS medium as described in the text. Crystal toxin was determined as described by Andrews et al. (1981).

1981; Lereclus et al., 1982; Stahly et al., 1978). Several aspects of *B. thuringiensis* plasmid biology are unique and worthy of mention in this context.

In some strains with many plasmids (some of which are very large), up to 20% of the total DNA coding capacity may be plasmid-borne. Most of the plasmids in *B. thuringiensis* are cryptic in that functions have not been assigned to them; indeed, most of the plasmids from these strains can be cured with no observable change in phenotype (Gonzalez et al., 1981). It is unlikely, however, that an organism would maintain this amount of unproductive DNA, so it is likely that these cryptic plasmids serve some purpose.

Plasmid incompatibility is the inability for two plasmids to coexist in the absence of selective

pressure. When two plasmids are of the same incompatibility group, they will not be maintained unless each contains a selective marker that can be used to assure that it is not lost. Because of the multiple plasmids found in *B. thuringiensis* isolates and because plasmid loss is not readily observed in these strains without some curing pressure, one must conclude that 1) there must be many incompatibility groups (at least 17) in *B. thuringiensis*; 2) that in cases where two or more of the plasmids are of the same incompatibility group, there must be some as of yet unrecognized selective pressure to maintain these plasmids; and/or 3) *B. thuringiensis* contains some mechanisms to defeat normal incompatibility groupings. In any case, further investigation of the multiple plasmids contained in *B. thuringiensis* should increase our understanding of plasmid incompatibility in bacteria in general.

Finally, *B. thuringiensis* plasmids have been shown to be transferred with relatively high frequency between many bacilli, including *B. thuringiensis*, *B. cereus*, *B. megaterium*, and *B. anthracis* (Battisti et al., 1985; Gonzalez et al., 1982; Green et al., 1989). Further understanding of this process will greatly extend the understanding of genetic exchange in Gram-positive bacteria in general, and further define safety parameters for genetically engineered microbes released into the environment.

Transposons and Insertion Sequences. Lereclus et al. (1983) described a unique 4.2-kb DNA sequence that was found on several large toxin-coding plasmids of *B. thuringiensis*. This particular sequence (Th-sequence) was found as an insertion in the *Streptococcus faecalis* plasmid, pAMβ1, which was introduced into *B. thuringiensis* subsp. *berliner* 1715. The 4.2-kb DNA sequence resembled an insertion sequence (IS element) and was found in close proximity to the protoxin genes from several *B. thuringiensis* subspecies. A 1.3-MDa segment of DNA separated the Th-sequence from the subsp. *berliner* 1715 protoxin gene, and a similar DNA segment was located on the other extremity of the gene but in the opposite orientation. These DNA segments contained inverted repeat sequences and were referred to as IR*1*. When a plasmid carrying IR*1* and the Th-sequence was observed with an electron microscope, it appeared to be a transposon (Tn) (Lereclus et al., 1984). Therefore, the Th-sequence is now referred to as Tn*4430,* and is the first transposon isolated from the genus *Bacillus* (Lereclus et al., 1986).

This DNA segment is similar to the Tn3 family in structure and transpositional activity (Lereclus et al., 1986). In addition to its insertion properties, Tn*4430* has short terminal inverted repeats and promotes deletions adjacent to its insertion site similar to that observed with Class II elements (Lereclus et al., 1984, 1986). Nonetheless, the function of this transposon has not been identified. Similar inverted sequences, IR*1750* and IR*2150,* flanking the plasmid-encoded 68-kDa protoxin gene of subsp. *kurstaki* HD-73, have been identified (Kronstad and Whiteley, 1984). Southern hybridization confirmed that these sequences were located in close proximity to the protoxin genes from 14 other strains of *B. thuringiensis*, and it was believed that IR*1750* and IR*2150* may be insertion sequences that mediate transposition. Nucleotide sequencing of one IR*1* element revealed all the characteristic features of an insertion sequence and was referred to as IS*231* (Mahillon et al., 1985). IS*231* (1656 bp) was isolated from subsp. *berliner* 1715 and found to be closely linked to the protoxin gene. It is delineated by two 20-bp inverted repeats flanked by two 11-bp direct repeats. IS*231* contains an open reading frame that spans almost the entire sequence, and DNA sequence homology has been observed between IS*231* and the *E. coli* IS*4* element.

Mahillon et al. (1987) sequenced two other insertion regions flanking the subsp. *berliner* 1715 crystal toxin gene and showed them to be variants of IS*231*. These sequences were referred to as iso-*231* elements. When the nucleotide sequences surrounding the iso-*231* elements were compared to IS*231,* it was shown that a structural association existed between these elements and the transposon Tn*4430.* It appeared that two IS*231* elements transposed into Tn*4430* where both the IS*231*s and the transposon Tn*4430* remained structurally intact. This structural association between IS*231* and Tn*4430* is similar to the organization of class I mobile genetic elements (i.e., Tn*5* or Tn*10*), and although the exact function of the IS*231* elements is unknown, it is thought they control Tn*4430* transposition (Mahillon et al., 1987).

In summary, the presence of repeated elements around crystal protein genes may provide two possible mechanisms for the dispersal of the toxin gene on different plasmids and for the integration of this gene into chromosomal DNA. The evidence for transposition of the Th-sequence into other plasmids and the arrangement of the repeated elements suggest that the toxin gene could undergo transposition. Alternatively, the presence of repeated elements on many different plasmids and on chromosomal DNA would also provide a mechanism for rearrangements of DNA. Further research is required to understand transposition in *B. thuringiensis* and to provide an increased understanding of the role of these repeated elements.

GENETIC TRANSFER SYSTEMS. Although there is substantial literature regarding the genetics of *Bacillus thuringiensis*, methodology for the introduction of foreign or cloned DNA into this organism is minimal. Three general mechanisms for introduction of DNA are usually described, transformation, conjugation, and transduction. All three forms of genetic exchange involving *B. thuringiensis* have been described in the literature.

Several investigators have reported transformation of *B. thuringiensis* protoplasts using methods similar to those used in *B. subtilis* (Chang and Cohen, 1979). Martin et al. (1981), for example, used a protoplast transformation protocol to transform *B. thuringiensis* with plasmid pC194. Unfortunately, they were unable to detect extrachromosomal pC194 in regenerated transformants and provided evidence that the plasmid integrated into the chromosome. Later, other workers physically identified the stable presence of pC194 in various transformants (Crawford et al., 1987; Fischer et al., 1984; Heierson et al., 1987). Moreover, other plasmids have been inserted into cells of *B. thuringiensis* by protoplast transformation (Alikhanian et al., 1981; Miteva et al., 1981). The methods used by different investigators for protoplast generation has varied. Fischer et al. (1984) used protoplasts generated by lysozyme treatment, whereas Heierson et al. (1987) and Crawford et al. (1987) generated protoplasts by using conditions that induced limited autolysin formation.

High voltage electroporation has been used in many systems, including plant cells, animal cells, and bacteria for introduction of foreign DNA. Recently, Bone and Ellar (1989) demonstrated use of this technique to transform several plasmids into *B. thuringiensis*. The method is rapid and effective, and yields transformation efficiencies in the range of 10^2–10^5/µg of DNA.

The naturally occurring conjugation systems in *B. thuringiensis* have already been discussed. Gonzalez et al. (1982), for example, described a natural plasmid transfer system that allowed them to more extensively analyze the relationship between crystal production and plasmid content. They noticed high frequency transfer of plasmids during logarithmic growth between parasporal crystal-positive (cry^+) strains and cry^- strains. For instance, when *B. thuringiensis* subsp. *kurstaki cry$^-$* recipients were mated with cry^+ *B. thuringiensis* subsp. *thuringiensis* donors, the *B. thuringiensis* subsp. *kurstaki* strains were converted to cry^+ phenotype. The size of the transmissible crystal-coding plasmid varied with the donor strain, and immunological analysis showed the *B. thuringiensis* subsp. *kurstaki cry+* transcipients to be hybrid strains, i.e., having the flagellar serotype of the recipient and crystals of the donor serotype.

Gonzalez and Carlton (1984), utilizing their high-frequency plasmid transfer system, genetically analyzed crystal toxin production in *B. thuringiensis* subsp. *israelensis*. They showed that *B. thuringiensis* subsp. *israelensis* contained eight plasmids ranging in size from 3.3–135 MDa. Curing studies showed that a 75-Mda plasmid was responsible for toxin production, because 15 B. thuringiensis subsp. *israelensis cry$^-$* isolates were shown to lack this 75-MDa plasmid. This conclusion was supported by transfer of the 75-MDa plasmid into a cry^- strain.

Transfer systems native to other bacteria can also be used for introduction of genetic information into *B. thuringiensis*. Franke and Clewell (1981) described a chromosome-borne tetracycline resistance element in *Streptococcus faecalis* strain DS16 that had the characteristics of a transposon. This 15–17 kb element, Tn*916,* was capable of transposition to several different conjugative plasmids containing hemolysin genes (pAD1 and pOB1) at frequencies of approximately 10^{-6}. Moreover, Tn*916* was also capable of transposition at low frequency (10^{-8} per recipient) from plasmid-free derivatives of strain DS16 to plasmid-free *S. faecalis* recipients. This transfer was resistant to the action of DNase, did not require homologous host-mediated recombination functions, and occurred by a conjugation-like event that required direct contact between the donor and recipient. Tn*916* (16.4 kb) is classified as a Class IV transposon (Kleckner, 1981). Tn*916* has been transferred to a number of streptococcal species by the filter mating technique (Franke and Clewell, 1981; Nida and Cleary, 1983; Wanger and Dunny, 1985; Weiser and Rubens, 1987). Furthermore, Tn*916* has been transferred by filter matings to *Staphylococcus aureus*, *Listeria monocytogenes*, *Bacillus anthracis*, *Clostridium difficile*, and *Mycoplasma hominis* (Hachler et al., 1987; Ivins et al., 1987; Jones et al., 1987; Kathariou et al., 1987; Roberts and Kenny, 1987). The conjugative transfer of Tn*916* in the absence of plasmid DNA occurs at a frequency of 10^{-5}–10^{-8} per donor, and DNA hybridization data has demonstrated that Tn*916* inserts into different sites on the recipient chromosome (Gawron-Burke and Clewell, 1982). Insertional mutagenesis using Tn*916* has been reported (Ivins et al., 1987; Kathariou et al., 1987; Nida and Cleary, 1983).

Naglich and Andrews (1988a) recently reported introduction of the *S. faecalis* transposon Tn*916* into *B. thuringiensis*. When introduced into *B. thuringiensis* by filter mating with *S. faecalis*, Tn*916* inserts into evidently random sites on the chromosome, as judged by Southern analysis; insertion into plasmid DNA has not been

observed. In contrast, when Tn*916* was transferred from one strain of *B. thuringiensis* subsp. *israelensis* to an antibiotic-resistant derivative of the same strain, insertion occurred at one site, suggesting that in this case DNA probably integrated into the chromosomal DNA by homologous recombination.

To enhance the transfer frequency, Tn*916* was first introduced into *B. subtilis* and then transferred to an antibiotic-resistant strain of *B. thuringiensis* subsp. *israelensis*. With this method, transfer occurred at frequencies 10– to 100-fold greater than when transfer was from *S. faecalis*. As in the case of transfer from *S. faecalis*, Tn*916* inserted randomly into the chromosome of *B. thuringiensis*, but, as in the previous experiments, not into plasmid DNA (Naglich and Andrews, 1988b). Several lines of evidence support the conclusion that DNA transfer is a Tn*916*-dependent conjugal event. 1) Transfer of genetic material was only observed when the cells were impinged on a filter and then grown on solid medium; transfer was not observed in broth. 2) Incorporation of high levels of DNase into the medium upon which the filter was placed did not prevent the process. 3) Transfer was Tn*916*-dependent; no DNA transfer was observed in the absence of the transposon, which carries its own mobilization functions.

The *Staphylococcus aureus* plasmids, pC194 and pUB110, were introduced into *B. thuringiensis* subsp. *israelensis* by using Tn*916* as a mobilizing agent. Transfer of pC194 occurred only when *B. thuringiensis* subsp. *israelensis* was mated with a *B. subtilis* donor that contained both pC194 and Tn*916;* plasmid transfer was not observed in the absence of the transposon. *B. thuringiensis* transconjugants resistant to chloramphenicol (the plasmid marker, Cm^r) and tetracycline (the transposon marker, Tet^r) were detected at a frequency of 2×10^{-6} per recipient cell, whereas the Tet^r phenotype but not the Cm^r phenotype was observed at a frequency of 1×10^{-4}. The converse, Cm^r but not Tet^r, was observed at a frequency of 3×10^{-5}. Transconjugants were detected in filter matings only, not in broth. Southern hybridization data indicated that the transposon was integrated into the *B. thuringiensis* chromosome, whereas the pC194 probe hybridized to a covalently closed circle form of the same size as pC194. The Tet^r phenotype was maintained during serial passage of *B. thuringiensis* without selection, whereas the Cm^r phenotype was not. The plasmid pUB110, also from *S. aureus*, can be transferred at similar frequencies, but mobilization of the plasmid pE194 has not been detected (Naglich and Andrews, 1988b).

Transduction in *B. thuringiensis* has also been reported. Lecadet et al. (1980), for example, demonstrated transfer of genetic markers in *B.* *thuringiensis* using the transducing phage CP54. A similar phage, CP51, has been shown to mediate generalized transduction in *B. thuringiensis*, as well as in *B. cereus* and *B. anthracis* (Thorne, 1978). CP51 transduces chromosomal markers at frequencies ranging from 10^{-6}–10^{-7} and can carry up to 60 kb of DNA (Yelton and Thorne, 1971). Also, phage CP51 induces movement of plasmid-borne DNA into *B. thuringiensis* (Ruhfel et al., 1984).

Biotechnological Applications

Despite the relatively large number of insect pathogens that have been proposed as insecticides, those products formulated with *B. thuringiensis* are the most extensively and widely used today. There have been recent reviews discussing the biotechnology of *B. thuringiensis* (Andrews et al., 1987; Bulla et al., 1985). Accordingly, only a few selected topics will be discussed herein.

Insecticides formulated with *B. thuringiensis* are extremely specific; they affect only a limited range of insects and are nontoxic to predatory insects, birds, and mammals, thus providing significant advantages over chemical insecticides. Because of their lack of toxicity to humans, these insecticides can be applied just prior to harvest, a time when an insect infestation can cause extreme damage to the crop in a short time. Because no human toxicity has been reported, there can be immediate field entry. Moreover, there is minimal risk of toxicity to those who apply the pesticide, and there is no significant risk to humans living near the application area. The latter is particularly important when mosquitoes must be controlled near residential areas.

There are, however, significant problems associated with the use of these insecticides. One is that they exhibit poor stability under field conditions. The insecticidal activity of pesticides formulated with *B. thuringiensis* has a half-life of 1–2 days (Beegle et al., 1981; Sorenson and Falcon, 1980). Therefore, frequent reapplications are required. At least in part because of this short field life, such insecticides are expensive to use when compared to the more widely used organic pesticides. Insecticidal activity is associated primarily with the crystal toxin rather than the spores (West et al., 1984). In a soil environment, the low stability of crystal toxin is probably due to degradation by soil microflora (West, 1984). The lack of the toxin's stability on foliage is due at least in part to physical removal by precipitation. Research is needed to discover methods for stabilizing the crystal toxin.

Bulla et al., (1985) discussed three possible reasons that *B. thuringiensis* insecticides have not been more widely used. 1) For many insect control situations, broader-spectrum insecticides

are preferred because of the multiple pests found on crops. Moreover, growers often believe that contact pesticides are more effective and have found that more cost-effective alternatives are available. Thus the marketplace is generally viewed as too small to attract widespread interest among agricultural companies. 2) Many agricultural companies are adapted to working with chemical pesticides and have difficulty working with a product of biological origin. 3) There has been little or no patent protection available to producers. The impact of the Chakrabarty court decision that allows patenting of genetically modified microbes remains unclear.

Despite these difficulties, *B. thuringiensis* has been the subject of intensive investigation using the tools of biotechnology. Because of the highly selective toxic activity associated with *B. thuringiensis*, biotechnologists see a potential to develop safe, effective, and economically feasible insect control agents. Research into new ways to use *B. thuringiensis* and/or its toxic products has focused in three general areas.

One area of interest centers on the problem of narrow host range. Although the advantages of such a narrow host range are clear, limited toxicity also restricts the use of *B. thuringiensis* as an insecticide. Wabiko et al. (1986), for example, compared the DNA and derived protein sequences of the crystal toxin genes from two strains of *B. thuringiensis* having different insect specificities. Interestingly, there were several areas of strong protein homology and three areas in which striking differences were clustered. The authors speculated that these three areas might be important for genetic determination of the insect specificity of the toxin. At the present time much effort is being exerted to understand the basis for insect specificity of the *B. thuringiensis* toxin in the belief that it may be possible to alter or expand the host range.

An alternative approach is that the toxin gene could be placed in another bacterium that would live longer in the environment, multiply, and, thus, remain in or on the insect's food supply for a longer period of time. In a recent review, Andrews et al. (1987) described three possible examples of this approach. One approach, for example, was to stabilize the subsp. *israelensis* toxin by cloning its gene into *Bacillus sphaericus*, an organism which is much more stable in water environments than *B. thuringiensis* var. *israelensis*. Another approach is to clone the toxin genes into pseudomonads, organisms known to adhere to certain parts of plants. Both living and killed strains containing toxin genes have been described. Also, it is possible to clone the subsp. *israelensis* toxin gene into cyanobacteria (Angsuthanasombat and Panyim, 1989). Such bacteria should both replicate in the water envi-

ronment and serve to make the mosquito larval food supply toxic.

Finally, the *B. thuringiensis* toxin gene can be directly cloned into and expressed in plant systems. Indeed, insect-resistant transgenic plants containing the *B. thuringiensis* toxin gene have been reported (Fischhoff et al., 1987).

Bacillus sphaericus

Although aerobic bacilli that produce round spores were described early in this century, the isolation of a strain that was pathogenic to mosquitoes and matched the description of *Bacillus sphaericus* did not occur until 1964 (Kellen and Meyer, 1964). This strain and subsequent isolates all possess the phenotypic characteristics typical of the species (see Chapter 76). Both pathogenic and nonpathogenic strains are aerobic bacilli producing round, terminally located spores that swell the sporangium. The spores vary in size and somewhat in shape (round to slightly oval) depending upon growth conditions. These bacteria are easily distinguished microscopically and physiologically from the other well-known mosquito pathogen, *B. thuringiensis* subsp. *israelensis*. The cells and spores of *B. sphaericus* are smaller than those of *B. thuringiensis* and the former species is much less active in its metabolism of a variety of substrates than is the latter. *B. sphaericus* is similar to *B. thuringiensis* in that the insect pathogenicity of each is mediated by the production of toxin.

Habitats and Isolation

The first isolation of a *B. sphaericus* mosquito pathogen was made from moribund, fourth-instar larvae of *Culiseta incidens* collected in California (Kellen and Meyer, 1964; Kellen et al., 1965). Additional isolates have also been obtained from dead mosquito larvae (Singer, 1973). More recently, pathogenic isolates have been obtained from black flies (Weiser, 1984), from caterpillars and grasshoppers (Lysenko et al., 1985), and from snails (de Barjac et al., 1988). These isolates were shown to be pathogenic for mosquitoes but lacked pathogenicity for the insects from which they were obtained. There was no indication that the snail isolate had been tested for pathogenicity to snails. *B. sphaericus* mosquito pathogens have also been obtained from mud taken from pools, from the soil of a dried stream bed (Brownbridge and Margalit, 1987), and from a loamy soil (de Barjac et al., 1988). Since this bacterium is not an obligate parasite and since there is no indication of marked differences in growth rates or metabolism between pathogenic and nonpathogenic

strains, it seems likely that pathogens may be recovered from the same soil and aquatic habitats that are occupied by the nonpathogens. However, it is known that the pathogenic strains can multiply in the cadavers of mosquito larvae that have been killed by the larvicidal toxin (Charles and Nicolas, 1986; Davidson et al., 1975, 1984). Thus, it is likely that larger populations of the pathogens may be found in aquatic habitats that contain dead or dying larvae.

Isolation of pathogenic *B. sphaericus* from dead larvae can be performed by crushing larvae in sterile water or buffer and streaking the homogenate onto a proteinaceous medium such as brain heart infusion agar or nutrient agar supplemented with 0.05% yeast extract. A medium containing amino acids or protein hydrolysate is required because *B. sphaericus* cannot utilize sugars as a carbon source (Russell et al., 1989). The inclusion of yeast extract in media is useful because many strains of *B. sphaericus* are auxotrophic for vitamins, frequently biotin and thiamine (White and Lotay, 1980). If isolations are made from mud or soil where the population of the pathogens might be lower than in larval cadavers, it is useful to heat the suspension to kill contaminating vegetative cells before streaking. *B. sphaericus* has been reported to be resistant to streptomycin, chloramphenicol, lincomycin, and bacitracin (Burke and McDonald, 1983; Kalfon et al., 1986; Yousten et al., 1985) and these antibiotics may be useful additions to selective media. A defined medium (BATS) utilizing arginine as the sole carbon and nitrogen source and streptomycin as a selective agent allowed growth of pathogenic strains of *B. sphaericus* but did not allow growth of 68% of the nonpathogenic strains tested. It also did not allow growth of several other aerobic, spore-forming bacteria.

BATS Defined Medium for Growth of *Bacillus sphaericus* Mosquito Pathogens (Yousten et al., 1985)

The medium contains per liter:

Na_2HPO_4	5.57 g
KH_2PO_4	2.4 g
$MgSO_4 \cdot 7H_2O$	0.05 g
$MnCl_2 \cdot 4H_2O$	0.004 g
$FeSO_4 \cdot 7H_2O$	0.028 g
$CaCl_2 \cdot 2H_2O$	0.002 g
L-Arginine	5.0 g
Thiamine	0.02 g
Biotin	2.0 µg
Streptomycin sulfate	0.1 g

The arginine, biotin, thiamine and streptomycin are prepared as a filter-sterilized stock solution. The Mg^{2+}, Mn^{2+}, Fe^{2+}, and Ca^{2+} salts are prepared as an acidified (0.03% [vol/vol] concentration of H_2SO_4), autoclaved stock solution. These two stock solutions are added to the autoclaved phosphate salts solution when the latter has cooled to 50°C.

At present there is no way to distinguish pathogenic strains from nonpathogenic strains of *B. sphaericus* by colony morphology or by any simple biochemical test. New isolates grown on solid media are examined microscopically for round spores and then grown in a liquid medium allowing good sporulation. This is followed by bioassay of the cell mass using susceptible mosquito larvae, e.g., *Culex quinquefasciatus*. Two rather similar media that have been widely used for obtaining good sporulation and concurrent toxic production are NYSM broth (Myers and Yousten, 1980) and MBS broth (Kalfon et al., 1983).

NYSM Broth (Myers and Yousten, 1980)

Nutrient broth	8.0 g
Yeast extract	0.5 g
$MgCl_2 \cdot 6H_2O$	0.2 g
$MnCl_2 \cdot 4H_2O$	10.0 mg
$CaCl_2 \cdot 2H_2O$	0.1 g

Identification

THE PLACE OF THE PATHOGENIC STRAINS WITHIN THE SPECIES.   Despite the phenotypic similarities and the same GC content (35–37 mol%) found in the pathogenic and nonpathogenic strains of *B. sphaericus*, large amount of genetic diversity appear to exist within this "species." The first indication of this diversity was given by Seki et al. (1978) and was greatly expanded to cover both pathogens and nonpathogens by Krych et al. (1980). Analysis using DNA hybridization revealed five major homology groups within the species. One of these groups (II) was subdivided into groups IIA and IIB. The former was composed of the seven mosquito pathogens included in the study, whereas all of the strains in the other homology groups were nonpathogenic. F. G. Priest (personal communication) used DNA hybridization to study additional pathogenic strains and obtained similar results. However, other than pathogenicity itself, no single phenotypic test allowed unambiguous differentiation of pathogens from nonpathogens. de Barjac et al. (1980) carried out numerical analysis of growth on 160 substrates to identify three groups; one of these contained nine pathogens and one nonpathogen and the other two groups contained 25 nonpathogens. Williston and Singer (1987) were able to separate six pathogens from the type strain of the species (a nonpathogen) and one other nonpathogen by electrophoretic analysis of aminopeptidase activity on four L-amino acid-beta naphthylamide substrates. F. G. Priest (personal communication) used a group of 13 phenotypic tests to successfully differentiate pathogenic strains from the closely related nonpathogenic strains of homology group IIB. He

found that adenine utilization was the single test that most often correlated with pathogenicity. Although the DNA homology studies clearly indicate that the mosquito pathogens are not the same species as the type strain of *B. sphaericus* (ATCC 14577), it is not clear if the pathogens are a separate species from the nonpathogens of homology group IIB. It is not yet known if the gene for the toxin responsible for pathogenicity is located on the chromosome or on a plasmid. If it is located on a plasmid, speciation of the pathogens would leave one in the same unsatisfactory position as is presently the case with *B. thuringiensis* and *B. cereus*.

DIVERSITY AMONG THE MOSQUITO PATHOGENIC STRAINS. The pathogenic strains of *Bacillus sphaericus* have been subdivided by serotyping (H antigens), bacteriophage typing, serotyping based upon antigenicity of the cell surface protein (the S layer), and the level of toxicity to mosquito larvae. These methods have shown remarkable agreement in the establishment of groups of strains.

Flagellar serotyping (H antigens) has identified six groups among the pathogenic strains (de Barjac et al., 1980; 1985, 1988). Three of these serotypes (H5a,5b; H25; and H6) contain highly toxic strains, whereas the other three serotypes contain weakly toxic strains. Serotype H6 is unique in that it also contains some nontoxic strains (de Barjac et al., 1988).

Several lytic bacteriophages have been isolated for the *B. sphaericus* pathogens. These phages have been used to group the strains, and the groups identified by phage typing correspond closely to the groups identified by flagellar serotyping (Yousten, 1984; Yousten et al., 1980). Phage group 3 contains the highly toxic strains of serotypes H5a,5b and H6.

The bacteriophages have been shown to attach to the bacterial cells via a high molecular weight glycoprotein (Lewis and Yousten, 1988). This protein is present in a fine, linear array (the S layer) on the cell surface of the mosquito pathogens (Lewis and Yousten, 1987). This is in contrast to the tetragonal arrangement of the S layer on the type strain, ATCC 14577. Immunological analysis of this protein revealed that it was distinct for each of the bacteriophage groups, although in several cases bacteriophages were neutralized by the protein from strains on which the phages failed to replicate. Thus, although the proteins are distinct for each phage group, they alone do not determine those groups. The gene encoding the S-layer protein from *B. sphaericus* 2362 has been cloned and sequenced (Bowditch et al., 1989). The nucleotide sequence indicated an open reading frame coding for a protein of 1,176 amino acids with a molecular weight of 125 kDa. A 30 amino acid leader peptide is cleaved from the 125-kDa protein during secretion resulting in a 122-kDa protein present on the cell surface. The 12 N-terminal amino acids of the 122-kDa S-layer protein and those of a 110-kDa larval toxin are identical. This larval toxin, which at one time was thought to be present in the parasporal body, thus appears to be derived from the S layer. Immunological studies also support this interpretation (Bowditch et al., 1989). Amino acid sequence comparisons of the 125-kDa protein with the S-layer proteins of other bacteria, revealed no sequence similarity to those of *Halobacterium halobium* or *Deinococcus radiodurans* but did show significant sequence similarity to the N-terminal portion of the "outer wall protein" of *Bacillus brevis* 47.

Ecophysiology

The major aspect of ecophysiology discussed below relates to the toxins produced by *B. sphaericus* strains that are mosquito pathogens. As indicated above, one of the mosquito larval toxins appears to be derived from the cell wall-associated S-layer glycoprotein. However, the toxin thought to be most important for pathogenicity is primarily located in a parasporal body or crystal (Davidson and Meyers, 1981). This inclusion body appears in the cell during the time of engulfment of the forespore by the forespore septum. Thin sections of the inclusions revealed a crystalline lattice structure having striations at a 6.3-nm interval (de Barjac and Charles, 1983; Yousten and Davidson, 1982). Unlike the paraspores of *B. thuringiensis*, which form outside the exosporium, those of *B. sphaericus* are partially enclosed by an elongated exosporium. This results in many of the paraspores remaining attached to the endospore upon lysis of the mother cell at the completion of sporulation. When paraspores were fed to mosquito larvae, the protein matrix of the paraspores rapidly dissolved in the alkaline midgut leaving a meshlike envelope in the shape of the paraspore (Yousten and Davidson, 1982). The composition of the parasporal envelope is unknown.

The matrix of the parasporal body is composed of two proteins: a 41.9-kDa protein that is toxic to mosquito larvae and to cultured mosquito cells, and a 51.4-kDa protein that is toxic to neither. Genes encoding these proteins have been cloned and sequenced from three highly toxic strains (Baumann et al., 1988; Berry and Hindley, 1987; Hindley and Berry, 1987, 1988). No sequence similarity was found between the *B. sphaericus* toxin and the Diptera- and Lepidoptera-active toxins of *B. thuringiensis* subsp. *israelensis* and *kurstaki,* respectively (Baumann

et al., 1988). The N-terminus of the toxin protein present in the paraspore is missing four amino acids as compared to the amino acid sequence deduced from the nucleotide sequence. It has been suggested that this deletion is produced by a *B. sphaericus* protease. Following ingestion of the 41.9-kDa toxin by mosquito larvae, the larval gut proteases remove an additional six amino acids from the N-terminus and approximately 20 amino acids from the C-terminus. This proteolysis enhanced the cytotoxicity of the protein for cultured mosquito cells (Broadwell and Baumann, 1987; Davidson, 1986; Davidson et al., 1987a). Interestingly, when the cloned 41.9-kDa toxin was produced in *E. coli*, it was not toxic to larvae unless it was combined with the 51.4-kDa (nontoxic) protein (Baumann et al., 1988).

In addition to the highly toxic strains, which produce a parasporal body containing the 41.9-kDa toxin, there are low-toxicity strains that do not produce a paraspore (Davidson and Myers, 1981). Probes that utilize the nucelotide sequence of the 41.9-kDa toxin did not detect these sequences in dot blots of the low toxicity strains (D. Wilcox, personal communication). The nature of the toxicity in these low toxicity strains is unknown and the possible relationship to the 110-kDa S layer-derived toxin remains to be determined.

The *B. sphaericus* toxin affects a variety of mosquito species from several genera but, unlike the toxin(s) from *B. thuringiensis* subsp. *israelensis,* it is not toxic to black fly larvae. It is much more toxic for mosquito larvae of the genus *Culex* than it is for *Aedes aegypti* (though certain other species of *Aedes* are quite sensitive). The degree of sensitivity to the toxin may be related to the ability of the toxin to bind to midgut cells in the larvae. Good binding of fluorescein-labeled toxin was observed in the gut of *Culex pipiens,* but there was no binding in the gut of *Aedes aegypti* (Davidson, 1989). The effects of the toxin have been studied both in mosquito larvae (Charles, 1987; Davidson, 1979; Singh and Gill, 1988) and in cultured mosquito cells (Davidson, 1986; Davidson and Titus, 1987; Davidson et al., 1987b). Although the pathological effects have been reported in detail for events occurring at the organ and cellular level, the mechanism of action of the toxin at the subcellular or molecular level is unknown.

Genetics

Although lytic bacteriophages have been isolated that use the mosquito pathogens as hosts, temperate phages capable of carrying out transduction have not been described. The phenomenon of lysogeny has not been demonstrated in these bacteria.

The procedures used to induce competence in *Bacillus subtilis* have not proven successful for carrying out transformation in *B. sphaericus*. However, plasmid-mediated transformation of polyethylene glycol (PEG)-treated protoplasts was performed by McDonald and Burke (1984). An improved PEG-protoplast transformation procedure using restriction-deficient strains of *B. sphaericus* 1593 produced about 1×10^3 transformants/μg of pUB110, pLT105, or pAMB1 DNA (Taylor and Burke, 1989). W. Burke (personal communication) also used electroporation for the introduction of plasmid DNA into *B. sphaericus*. Restriction and modification systems were suggested by the fact that in *B. sphaericus* 1593 the transformation efficiency was 10^4-fold greater when the plasmid DNA, pUB110, was isolated from *B. sphaericus* rather than *B. subtilis*. This was confirmed by agarose gel electrophoresis of pUB110 and PBC16 incubated with lysates from *B. sphaericus* and *B. subtilis*. The results indicated the restriction system is an isoschizomer of *Hae* III (McDonald and Burke, 1984; Burke, personal communication). Cloning vectors for the mosquito pathogenic strains are being constructed (Norton et al., 1985).

Conjugation between *B. sphaericus* 1593 and *Enterococcus (Streptococcus) faecalis* using the method of filter mating was carried out by Orzech and Burke (1984). The transfer process was more effective between *E. faecalis* and *B. sphaericus* than between strains of *B. sphaericus*. It was unaffected by either endogenous restriction enzyme activity or by the presence of exogenous DNase.

The reports of naturally occurring plasmids in the toxin-producing strains of *B. sphaericus* have provided somewhat conflicting information. Davidson et al. (1982) reported the presence of a single large plasmid in the highly toxic strains 1593 and 1881 but no plasmids in strains 1691 or 2362. Abe et al. (1983) found a single large plasmid in strain 1881 but no plasmids in strains 1593 or 1691. In the weakly pathogenic strain Kellen K, Davidson et al. (1982) found no plasmids but Abe et al. (1983) found five. Singer (1987) reported an approximately 75-MDa plasmid in the highly toxic strains 1593, 2362, and 2297 as well in the less toxic strain SSII-1. Strain 2297 also contained two smaller plasmids (3.4 and 3.2 MDa). A. A. Yousten (unpublished observations) obtained results similar to those of Singer. The approximately 75-MDa plasmid seems to be common among the highly toxic strains, but the plasmid is not restricted to them because it is also present in the much less toxic strain SSII-1. In *B. thuringiensis* the gene(s) for the toxin(s) are usually present on plasmids. However, this determination has not yet been made for the mosquito larval toxin of *B. sphaericus*.

Biotechnological Applications

The major biotechnological application of mosquito-pathogenic strains of *B. sphaericus* has been as a biological control agent.

Following ingestion of a mixture of spores and toxin-containing paraspores, the number of viable spores in the gut decreases until the death of the larva, which usually occurs about 24 h after ingestion of the toxin. At that time some unknown fraction of the spores germinate, grow vegetatively, and sporulate in the larval cadaver. This results in about a 10–100-fold increase in the number of spores compared to the number originally consumed (Charles and Nicolas, 1986; Davidson et al., 1984). Each larval cadaver seems capable of producing about 10^5–10^6 spores. This recycling of the spores in the cadaver may be related to the prolonged larval control reported for this bacterium compared to *B. thuringiensis* subsp. *israelensis* when sporulated cultures of these bacteria have been sprayed into water to control mosquito breeding (Singer, 1987). The attractiveness of *B. sphaericus* as a mosquito larvicide is related to its extended persistence in the water and to the unrelatedness of its toxin to that of *B. thuringiensis* subsp. *israelensis*. This latter characteristic might make it a useful alternative should resistance to the *B. thuringiensis* toxin appear. Efforts are being made to introduce toxin genes from *B. thuringiensis* subsp. *israelensis* into *B. sphaericus* with the goal of extending the lethal effects of the latter bacterium to *A. aegypti,* a species of mosquito quite resistant to the usual *B. sphaericus* toxin. This would also extend the environmental persistence of the *B. thuringiensis* toxin. An additional attempt to extend environmental persistence has been made by de Marsac et al. (1987), who cloned an 8.6-kb fragment of *B. sphaericus* 1593M DNA into the cyanobacterium *Anacystis nidulans R2,* using the shuttle vector pUC303. The resulting transformant was toxic to mosquito larvae, though at least 1000-fold less toxic than the *B. sphaericus* parent.

CHAPTER 1.2.18

The Genus *Bacillus*—Medical

W. EDMUND FARRAR AND ANNETTE C. REBOLI

Of the 34 species of the genus *Bacillus*, the two of greatest medical importance are *B. anthracis*, the causative agent of anthrax, and *B. cereus*, which causes food poisoning. Nonanthrax *Bacillus* species, including *B. cereus*, also cause a wide variety of other infections, and they are being recognized with increasing frequency as significant pathogens in humans. Species which have caused human disease include *B. cereus*, *B. alvei*, *B. megaterium*, *B. coagulans*, *B. laterosporus*, *B. subtilis*, *B. sphaericus*, *B. circulans*, *B. brevis*, *B. licheniformis*, *B. macerans*, *B. pumilus*, and *B. thuringiensis*. After *B. anthracis*, *B. cereus* is the most frequent human pathogen. *B. subtilis* has been used as a synonym for aerobic sporeformers other than *B. anthracis*, and many isolates described as *B. subtilis* in the early literature were probably *B. cereus* (Weinstein and Colburn, 1950).

Anthrax

Anthrax has a long and fascinating history. The disease in cattle is described in Egyptian and Mesopotamian writings of around 5000 B.C. (Dürst et al., 1986) and it may have been responsible for two of the plagues visited upon the Egyptians and their cattle in 1491 B.C. (the "murrain of beasts" and the "plague of boils and blains"), described in the ninth chapter of Exodus. In the *Georgics,* written around 37 B.C. Publius Vergilius Maro (Virgil) refers to anthrax infection in sheep, cattle, horses, and oxen, and in men handling wool from infected sheep (Dirckx, 1981). As a cause of "black bane" and "murrain," it caused heavy losses of cattle and sheep in England and Europe in Saxon and Medieval times, and may have contributed to the Black Death that ravaged Europe in the mid 14th century (Twigg, 1984). In 1613, there were approximately 60,000 human deaths from anthrax in southern Europe.

In a series of papers written in 1863 to 1864, Casimir Davaine presented evidence linking anthrax in animals and humans with certain bacteria found in the blood and tissues (Davaine, 1863a, 1863b, 1864; Davaine and Raimbert, 1864). In 1876, Robert Koch visualized anthrax bacilli in the blood and tissues of animals dying of anthrax, demonstrated that the bacillus could form spores that remained viable for long periods in hostile environments, and claimed credit for proving that the bacillus is the causative agent of anthrax (Koch, 1877). Louis Pasteur, in a series of papers beginning in 1877, isolated the anthrax bacillus in pure culture from animals, propagated the organism in serial cultures, and reproduced the disease in experimental animals (reprinted in Vallery-Radot, 1939). It was thus Pasteur who fulfilled "Koch's postulates" in establishing a causal relationship between the anthrax bacillus and anthrax (Carter, 1988).

Because of vaccination programs and improved practices of raising livestock, anthrax has become a rare disease in many industrialized countries; an average of only two or three cases per year have been reported in the United States during the past 20 years. Most cases in industrialized countries are associated with exposure to animal products, especially goat hair, imported from Iran, Turkey, Pakistan, and Sudan, where anthrax remains common among domestic livestock. Worldwide anthrax remains an important disease, with an estimated 20,000 to 100,000 human cases occurring each year (Glassman, 1958). Recent outbreaks of human infection have been reported from Zimbabwe (Davies, 1982, 1983, 1985; Turner, 1980); Turkey (Doganay et al., 1986); Thailand (Sirisanthana et al., 1984); Bangladesh (Samad and Hoque, 1986); Afghanistan (Arya et al., 1982); Tanzania (Webber, 1985); Ethiopia (Seboxa and Goldhagen, 1988); and Uganda (Ndyabahinduka et al., 1984). During the civil war in Zimbabwe in 1979 to 1980, when medical services and animal vaccination programs were disrupted, more than 6,000 human cases occurred, with approximately 100 deaths.

Because of the extraordinary stability of the spores of *B. anthracis* and their virulence following inhalation or ingestion, anthrax has received much consideration as a potential agent for use

---

This chapter was taken unchanged from the second edition.

in biological warfare. In 1979, a large outbreak of anthrax, possibly involving more than 1,000 people, occurred in and around Sverdlovsk, a large industrial city in the Ural Mountains of the Soviet Union (Wade, 1980). It was suspected that this outbreak might have resulted from an accident of some kind, possibly an explosion at a secret military laboratory where a biological warfare agent was being prepared. This assertion was denied by the Soviet Union, and 10 years later a delegation of Soviet officials visited the National Academy of Sciences in Washington, D.C. to explain that the epidemic had consisted primarily of cases of intestinal anthrax, traced to a large lot of contaminated bone meal used as cattle feed. According to Soviet officials, the human victims became ill after eating infected meat purchased on the black market (Marshall, 1988).

Habitat and Ecology

The spores of *B. anthracis* are extremely resistant to heat, cold, desiccation, and chemical disinfection and may remain viable in the soil of pastures for many decades. Certain fields in Europe have been associated with repeated epizootics of anthrax in grazing animals for more than 100 years. Although the soil is the ultimate reservoir of *B. anthracis*, its ecology is complex (Van Ness, 1971). A vegetative phase may be required in which the organisms multiply to a density sufficient to infect grazing animals. In suitable limestone soils, with pH above 6.0 and ambient temperature above 15.5°C, a spore-vegetative cell-spore cycle may be maintained indefinitely and livestock grazing on such pastures may become infected. In unsuitable areas, perhaps because of acidity or intense bacterial competition, both organisms and spores may be eliminated rapidly. "Incubator areas" may develop in depressions where water has stood long enough to devitalize or kill grass. Flooding of these areas may result in dispersal of spores over a wide expanse. Cattle dying with anthrax commonly discharge large numbers of anthrax bacilli from the nose, mouth, and intestinal tract, thus returning organisms to the soil. Sporulation and dispersal of spores may also occur when the carcass of an animal dying of anthrax is opened in the field, either for necropsy or for butchering in countries where such animals provide meat for human consumption (McKendrick, 1980). Pasteur et al. 1880 showed that earthworms can return anthrax spores from the buried carcasses of animals dying of anthrax to the surface of the soil. Mechanical dispersal of spores over short distances may occur via flies, and over long distances by vultures which have fed on the carcasses of infected animals (McKendrick, 1980; Davies, 1983).

Acquisition of anthrax by animals and humans occurs via spores; vegetative forms probably play no significant role in its transmission. Grazing animals often acquire anthrax during periods of drought, when the herds are forced to graze on spiny vegetation close to the ground and abrasions on the lips allow deposition of spores in the tissues; ingestion of spores along with vegetation is another route of infection. Fertilizers made from contaminated animal bones, hay, water, and animal feeds are additional sources of infection in animals. Biting flies may transmit anthrax among animals in some tropical countries but probably do not constitute an important source of infection worldwide.

Human cases of anthrax are acquired via contact with infected animals or animal products and may be classified as *agricultural* or *industrial*. Agricultural cases predominate in developing countries where there is an extensive agricultural economy and anthrax is enzootic in livestock. Outbreaks of human anthrax are almost always preceded by epizootics in cattle, as occurred in the large epidemic of human anthrax in Zimbabwe in 1979 to 1980. Nearly all cases of agricultural anthrax are of the cutaneous form and result from handling infected carcasses or animal products. In countries where animals dying of anthrax are consumed by humans, occasional cases of intestinal and oropharyngeal anthrax occur. An outbreak of 24 cases of oropharyngeal anthrax, and many cases of the cutaneous form, occurred in northern Thailand in 1982 as a result of individuals eating the meat of sick cattle and water buffaloes imported on the hoof from Burma (Sirisanthana et al., 1984). The role of biting insects in transmission of anthrax to humans remains controversial. Stable flies (*Stomoxys* spp.) and two species of *Aedes* mosquitoes have been shown to be capable of transmitting anthrax from infected guinea pigs to uninfected guinea pigs and mice (Turell and Knudson, 1987). During the 1979 to 1980 epidemic in Zimbabwe, several lines of evidence suggested that transmission occurred via the bites of stable flies and horse flies (Tabanidae): 1) the epidemic coincided with an explosive increase in the population of horse flies; 2) in children, who had little exposure to infected animal carcasses, there was an increased incidence of lesions on the head, neck, and face, where insect bites were common; and 3) a number of patients remembered an insect bite at the site where an anthrax lesion developed later (McKendrick, 1980; Davies, 1983). Person-to-person spread occurs very rarely if at all; there were no cases among the nursing staff and no evidence of cross-infection among patients during the Zimbabwe epidemic.

Industrial anthrax results from contact with spore-contaminated materials such as goat hair,

animal hides, wool and bones used in manufacturing processes, or finished products such as shaving brushes, bongo drums, and saddle blankets. Most cases are of the cutaneous type, but occasional cases of inhalation anthrax (woolsorter's disease) are seen (Brachman, 1980). Nearly all such cases occur in workers exposed to aerosols of anthrax spores during early processing of imported goat hair or hides, or less commonly wool. Very rarely the disease occurs in laboratory workers or in artisans working with imported animal hair or skins. There have been only two cases of inhalation anthrax in the United States in the last 20 years (18 cases during this century).

Anthrax in Animals

Anthrax is primarily a disease of herbivorous animals, especially cattle, sheep, horses, goats, and wild herbivores, although nearly all mammals are susceptible to the disease to some degree. Omnivores such as man and swine, and carnivores such as dogs, possess greater natural resistance to anthrax than do herbivores (Knudson, 1986).

Three forms of anthrax, peracute, acute/subacute, and chronic, are recognized in animals (Hunter et al., 1989). The peracute form is seen mainly in ruminants, especially cattle, sheep, and goats. The animals may develop cerebral anoxia and pulmonary edema, and death may occur suddenly.

Acute and subacute anthrax are characterized by fever, depression, convulsions, dyspnea, and hemorrhage from the mouth, nose, and anus, with death occurring approximately 24 h after the initial signs of illness. This form of anthrax is seen primarily in cattle, sheep, and horses. Pathologic findings include hemorrhage and edema in many different organs. In cattle and sheep, the spleen is enlarged with a "blackberry jam" appearance.

In chronic anthrax, seen most often in swine but also in horses, dogs, and cattle, the typical clinical signs are edema of the tongue and pharyngeal tissues with dyspnea and serosanguinous discharge from the mouth. Death due to asphyxia may occur. In swine, an intestinal form of chronic anthrax has been reported. At necropsy, edema and hemorrhage of the involved tissues is found.

Anthrax in Humans

Cutaneous anthrax accounts for approximately 95% of cases. Spores of *B. anthracis* are deposited underneath the epidermis via a minor cut or abrasion or insect bite. These spores then germinate, and the vegetative cells produce toxin. Following an incubation period of 2 to 7 days, a small papule which is often pruritic appears at the site where spores have been inoculated. This enlarges and within 24 to 48 h develops into an ulcer surrounded by vesicles. Eventually the characteristic black eschar develops, surrounded by edema which is often striking, especially with lesions on the face and neck. (The name "anthrax" is derived from the Greek *anthrakos*, which means "coal," as does *charbon*, the French term for the disease.) The lesion is painless. Most patients are afebrile and the white blood cell count is usually normal or only slightly elevated. More than 90% of lesions occur on exposed areas such as the face, neck, hands, and arms. Lymphangitis and regional lymphadenopathy may be present.

Cutaneous anthrax is usually a self-limiting disease and lesions heal spontaneously in 80 to 90% of cases (Knudson, 1986). In untreated cases, death may occur in 10 to 20% due to airway obstruction (especially with lesions of the face or neck) (Davies, 1982), bacteremia with shock and renal failure, or meningitis. Early and appropriate antibiotic therapy reduces the case fatality rate to less than 1%.

Internal forms of anthrax infection are much more difficult to diagnose, and the case fatality rate is much higher than in the cutaneous form, even with prompt and appropriate antibiotic therapy. *Inhalation* anthrax accounts for up to 5% of cases (Brachman, 1980). Most cases result from the inhalation of spores of *B. anthracis* during the processing of contaminated goat hair or wool. The infectious dose is high, probably on the order of 50,000 spores. After inhalation, the spores are ingested by alveolar macrophages and carried to the hilar lymph nodes. Germination and multiplication of the vegetative forms, with production of toxin, occur in the hilar nodes, resulting in edema and hemorrhage in the nodes and surrounding mediastinal structures. Eventually the bacilli may gain access to the blood via the lymphatics, with sepsis and subsequent metastatic spread. The clinical picture is typically that of a biphasic disease. The initial stage, which lasts 2 or 3 days, has an insidious onset with mild fever, malaise, fatigue, myalgia, nonproductive cough, and sometimes a sensation of precordial pressure, and is often mistaken for a viral respiratory infection. The second stage begins suddenly with acute dyspnea, cyanosis, diaphoresis, and stridor with rapid progression to a moribund state and death within 24 h. The characteristic roentgenographic picture is one of mediastinal widening due to lymph node enlargement. At autopsy hemorrhagic mediastinitis and lymphadenitis are found, often with little involvement of the lung parenchyma. Of the 18 cases of inhalation anthrax reported in the American literature since 1900, 16 were fatal.

Intestinal anthrax is very rare in humans and has never been documented in the United States (Nalin et al., 1977; Jena, 1980; Ndyabahinduka et al., 1984; Bhat et al., 1985). The disease follows ingestion of heavily contaminated, undercooked meat. Multiplication of organisms and production of toxin in the bowel wall and in mesenteric lymph nodes leads to edematous and hemorrhagic enteritis and lymphadenitis. The clinical picture is variable. Some cases present with gaseous distention and multiple fluid levels suggesting small bowel obstruction, with development of peritonitis. At surgery or autopsy, severe edema and gangrene of the bowel with multiple perforations and black necrotic areas may be found. The mesentery may be grossly edematous and hemorrhagic mesenteric lymphadenitis may be present. Other patients present with rapid development of hypovolemic shock and massive hemorrhagic ascites. The case fatality rate is 25 to 50% regardless of treatment.

Anthrax meningitis, another rare form of the disease, may occur as a result of the bacteremia which can accompany cutaneous or inhalation anthrax (Koshi et al., 1981; Trivedy, 1981; Chandramukhi et al., 1983; Dürst et al., 1986). In approximately one-half the cases, meningitis results from hematogenous dissemination from a cutaneous lesion. Nearly one-half of patients with inhalation anthrax develop meningitis. The clinical picture is that of a rapidly progressive acute bacterial meningitis. The case fatality rate, even with antibiotic treatment, is nearly 100%. At autopsy an acute hemorrhagic leptomeningitis, sometimes with subarachnoid, cortical or deep hemorrhages, or diffuse encephalitis, is found.

Oropharyngeal anthrax has occurred following ingestion of infected beef or water buffalo meat (Sirisanthana et al., 1984; Doganay et al., 1986). The primary lesion on the tongue, tonsil, or pharyngeal wall exhibits central necrosis and ulceration with surrounding edema and congestion. The neck on the involved side is markedly swollen with enlargement of cervical lymph nodes. The case fatality rate in patients treated with penicillin has varied from 15 to 50%.

A few cases of anthrax have been reported in cases of attempted abortion with spore-infected date stems or twigs, or following delivery in a stable, leading to hemorrhagic metritis, parametritis, and oophoritis, most ending in septicemia and death (Dutz and Kohout-Dutz, 1981).

Treatment and Prevention

The prognosis in cutaneous anthrax is good; 80 to 90% of cases resolve without specific antibiotic therapy. However, because of the potential complications of malignant edema, septicemia, shock, renal failure, and meningitis, patients with anthrax should receive prompt treatment, on the basis of clinical suspicion or visualization of organisms in Gram stains of specimens taken from the lesions. Treatment should not be delayed until bacteriologic confirmation is obtained. Penicillin G is the drug of choice in the treatment of anthrax (Knudson, 1986). An appropriate dosage regimen for treatment of cutaneous anthrax is two million units intravenously every 6 h for 2 to 4 days, until substantial improvement has occurred. At this time therapy can be changed to oral penicillin V, and treatment continued for a total of 7 to 10 days. Cultures of vesicle fluid become negative within a few hours after initiation of therapy with penicillin, but the lesion continues to evolve to the eschar phase. Systemic manifestations and local edema usually resolve promptly. Appropriate alternative choices for patients allergic to penicillin are erythromycin, tetracycline, and trimethoprim/sulfamethoxazole. Corticosteroids are recommended by many investigators when massive edema is present, and tracheostomy should be performed in patients with airway obstruction due to massive edema. Local surgical manipulation is ineffective and is contraindicated.

In patients with inhalation or gastrointestinal anthrax, severe sepsis or anthrax meningitis, the prognosis is poor regardless of treatment. In guinea pigs with experimental infection, once the level of bacteremia reaches three million organisms per milliliter of blood, eradication of the infection with antibiotics does not prevent a fatal outcome due to toxemia. This observation probably holds true for humans with septicemic anthrax (Keppie et al., 1955). The best hope is to begin therapy with high doses of penicillin G (12–20 million units per day, given intravenously in divided doses every 4 h) as soon as this type of infection is suspected. There is some experimental evidence that the combination of penicillin plus streptomycin (1–2 g per day intramuscularly) may be more effective in septicemic anthrax than penicillin alone (Lincoln et al., 1964). Chloramphenicol is not effective in the treatment of experimental septicemic anthrax and should not be relied upon for the treatment of systemic forms of infection.

In most countries, livestock at risk are immunized annually with commercial vaccines consisting of viable spores of the Sterne strain of *B. anthracis*, a nonencapsulated toxigenic variant which lacks the pX02 plasmid (Hambleton et al., 1984). This vaccine is effective and safe for use in many domestic animals (cattle, sheep, pigs, camels, buffaloes, and elephants) but progressive disease due to the vaccine strain has been observed in goats and llamas (Cartwright et al.,

1987; Sterne, 1988). The human anthrax vaccine licensed in the United States is produced by the Michigan Department of Public Health, and consists of aluminum hydroxide-adsorbed culture filtrate of the nonencapsulated toxigenic V770-NP1-R strain (composed primarily of protective antigen) (Ivins et al., 1986). Although guinea pigs immunized with the human vaccine produce high titers of antibody to protective antigen, only animals vaccinated with the Sterne strain are completely protected against challenge with highly virulent strains of *B. anthracis* (Little and Knudson, 1986). There appear to be at least two immunogenic vegetative cell-surface antigens present in the Sterne live vaccine which are not present in the human vaccine (Ezzell and Abshire, 1988). Modern studies have shown that the Pasteur vaccine strains (nontoxigenic, encapsulated) neither elicit antibody titers to any of the toxin components nor provide protection against challenge with virulent spores (Ivins et al., 1986). New approaches to development of more effective vaccines for human use include identification and incorporation of essential antigens and epitopes and transposon-induced mutagenesis to produce live vaccine candidate strains (Ivins and Welkos, 1988; Ivins et al., 1988).

When anthrax occurs in a herd, the source of infection must be determined and eliminated, and survivors should be treated prophylactically with antibiotics and the vaccination status brought up-to-date (Hunter et al., 1989). The affected farm should be quarantined for a period of at least 2 weeks following the last death from anthrax. Milk from unvaccinated febrile dairy cattle in the herd should be discarded and sick animals should be isolated. Animals dying of anthrax should be cremated or buried deeply after being covered with lime. Necropsy of dead animals should not be carried out in the field because of the risk of contaminating the soil with spores. Cases of anthrax in animals and humans should be reported to the appropriate health authorities.

Virulence Factors of *B. anthracis*

Fully virulent strains of *B. anthracis* possess two unique virulence factors: a poly-D-glutamic acid capsule (Green et al., 1985), which inhibits phagocytosis, and a tripartite toxin composed of protective antigen (PA), edema factor (EF) and lethal factor (LF) (Stephen, 1981; Leppla, 1988). Capsules are produced by virulent strains of *B. anthracis* growing in vivo, and by cells grown on media containing serum or bicarbonate or both and incubated in a CO_2-enriched atmosphere. The colonies of organisms that produce capsules appear mucoid, whereas colonies of organisms grown in the absence of serum or bicarbonate

fail to produce capsules and appear rough (Green et al., 1985).

The existence of an anthrax toxin was first clearly demonstrated by Smith et al. (1955), who produced local edema and death with injections of sterile plasma from infected guinea pigs. Studies by American and British investigators during the ensuing decade showed that the toxin contained three separate components (Stephen, 1981). The individual toxin components have no known biological effects when administered alone, but EF injected with PA into the skin of rabbits or guinea pigs causes local edema, and PA injected with LF into rats causes death in as little as 60 min. EF and LF are mutually inhibitory, suggesting that they compete for the same binding site on PA (Ezzell et al., 1984). Protective antigen, so-called because its injection into experimental animals results in protective immunity, binds to cell-surface receptors to produce an uptake system that can be used by both EF and LF to gain access to the cytoplasm. "Edema toxin" (EF + PA) and "lethal toxin" (LF + PA) thus resemble the A-B enzyme-binding structures characteristic of many well-studied bacterial toxins (Middlebrook and Dorland, 1984). After PA, analogous to the B chain, binds to a specific membrane receptor on the surface of a eukaryotic cell, it is cleaved at a single site, exposing a binding site for the other toxin component. The membrane-bound fragment of PA then binds to EF or LF and mediates the entry of the active moiety into the cytosol from an acidified endocytic vesicle. This fragment of PA has been shown to have channel-forming activity in planar phospholipid bilayers, and such channels may provide an aqueous pore in the endosomal membrane through which EF and LF enter the cell (Blaustein et al., 1989).

EF has been found to be a calmodulin-dependent adenylate cyclase that elevates cyclic AMP levels approximately 200-fold above normal in Chinese hamster ovary cells (Leppla, 1982, 1984). Local edema, a typical sign of anthrax, may be directly related to adenylate cyclase activity associated with EF. The increase in intracellular cAMP caused by this toxin may lead to edema in a manner analogous to the loss of water in the intestine caused by cholera toxin, which also increases intracellular cAMP (Leppla, 1982). EF + PA also inhibits phagocytosis of anthrax bacilli by polymorphonuclear leukocytes, and blocks both particulate and phorbol myristate acetate-induced chemiluminescence in polymorphonuclear leukocytes (O'Brien et al., 1985). These effects are accompanied by an increase in intracellular cAMP levels. The findings suggest that EF + PA may increase host susceptibility to anthrax by suppressing polymorphonuclear leukocyte function. The

dependence of EF activity on calmodulin, a substance found only in eukaryotic cells, suggests that EF did not evolve from a bacterial enzyme but from a eukaryotic adenylate cyclase, the gene for which was adventitiously transferred into *B. anthracis* and retained because it made the bacteria more virulent (Leppla, 1984). EF also exhibits substantial DNA homology and immunological relatedness with the *Bordetella pertussis* adenylate cyclase toxin (Escuyer et al., 1988). However, cytochalasin D, which interferes with endocytosis, and both ammonium chloride and chloroquine, which prevent acidification of endosomes, block intoxication of Chinese hamster ovary cells by EF, but not by pertussis adenylate cyclase toxin (Gordon et al., 1988).

The mechanism of action of LF is poorly understood. LF is lethal for many species of experimental animals and is assumed to be the major factor causing death in anthrax. No enzymatic activity has yet been associated with LF, and the nature of the intracellular target of LF is unknown. Certain macrophages and a mouse macrophage-like cell line are lysed at low concentrations of LF, but most cells are resistant (Singh et al., 1989). Resistant cells may either lack the intracellular target of LF or fail to process LF to an active form. There is evidence that PA may also be required for full activity of LF at a stage subsequent to endocytosis. LF is also calmodulin-dependent, and calcium is required at several steps for the expression of its effect (Bhatnagar et al., 1989).

Virulent strains of *B. anthracis* contain two large plasmids, pX01 and pX02 (Mikesell et al., 1983; Green et al., 1985; Kaspar and Robertson, 1987). Both plasmids are required for full pathogenicity, and strains which contain only one of these plasmids are avirulent. pX01 (174 kb pairs) encodes all three components of the anthrax toxin and pX02 (95 kb pairs) encodes the poly-D-glutamic acid capsule. The avirulent Sterne vaccine strain, which is pX01$^+$/pX02$^-$, produces toxin but no capsule and is used effectively as a live veterinary vaccine. The heat-attenuated Pasteur vaccine strains form capsules but are unable to produce toxin. Some rough variants of the Pasteur strains lack pX02, but others contain this plasmid. Reversion to mucoid colonies may be observed in strains that have retained pX02, but reversion of those cured of the plasmid is never observed. Pasteur probably cured his strains of plasmid pX01 by heat attenuation to produce his vaccine for immunization of cows and sheep.

The genes encoding all three toxin components have been cloned in *Escherichia coli* (Vodkin and Leppla, 1983; Robertson and Leppla, 1986; Mock et al., 1988; Tippetts and Robertson, 1988), and the base sequences for the PA and EF genes have been determined (Robertson et al.,

1988; Welkos et al., 1988). The PA gene has been cloned in *B. subtilis*, and immunization with the live recombinant strains protected guinea pigs from lethal challenge with virulent *B. anthracis* spores (Ivins and Welkos, 1986).

Bacillus cereus Food Poisoning

B. cereus has been recognized as an agent of food poisoning for the past several decades (Hauge, 1955). Between 1972 and 1986, 52 outbreaks of food-borne disease associated with *B. cereus* (1.9% of the total) were reported to the Centers for Disease Control (CDC). *B. cereus* strains cause two types of food-poisoning syndromes. These are true intoxications rather than infections. One type is characterized by nausea and vomiting (100%) and abdominal cramps (100%) and has an incubation period of 1 to 6 h (Terranova and Blake, 1978). This type has been referred to as the "emetic syndrome" or the short-incubation form. It resembles *Staphylococcus aureus* food poisoning in symptomatology and the short incubation period.

The second type of *B. cereus* food poisoning is manifested primarily by abdominal cramps (75%) and diarrhea (96%) with an incubation period of 8 to 16 h (Terranova and Blake, 1978). Diarrhea may be small volume or profuse and watery. This type is the "diarrheal syndrome" or long-incubation form (Mortimer and McCann, 1974) and resembles food poisoning caused by *Clostridium perfringens*. The illness usually lasts less than 24 h. In a few patients symptoms may last longer (2–10 days) (reference is not an exact matchGiannella and Brasile, 1979).

The short-incubation form is caused by a preformed heat-stable enterotoxin of molecular weight less than 5,000 which is produced by some *B. cereus* strains and which causes vomiting when fed to monkeys (Melling et al., 1976). The mechanism and site of action of this toxin are unknown (Turnbull et al., 1979b). The long-incubation form of illness is also enterotoxin-mediated. This toxin is produced in vivo (accounting for the longer incubation period), is heat-labile, and has a molecular weight of approximately 50,000 (Turnbull et al., 1979b). It activates intestinal adenylate cyclase and causes intestinal fluid secretion (Turnbull, 1976). It appears to have cytotoxic properties in rabbit small intestine and in guinea pig skin (Turnbull, 1976; Turnbull et al., 1979b).

B. cereus food poisoning occurs year round and is without any particular geographic distribution. The short-incubation form is most often associated with fried rice that has been cooked and then held at warm temperatures for several hours. The disease is often associated with

Chinese restaurants, especially in Europe, where leftover rice is often held overnight at room temperature because cooked rice which has been refrigerated is difficult to toss into beaten eggs. Growth of *B. cereus* in rice under similar experimental conditions has been documented (Gilbert et al., 1974). In one reported outbreak, the vehicle was macaroni and cheese made from powdered milk that was the source of the organism (Holmes et al., 1981). The short-incubation type is most often caused by serotype 1 strains (Gilbert and Parry, 1977) probably because they are more heat resistant than strains of other serotypes (Parry and Gilbert, 1980).

Long-incubation *B. cereus* food poisoning is frequently associated with meat or vegetable-containing foods. *B. cereus* contaminates raw meats, vegetables, and milk products. It has been isolated from 50% of dried beans and cereals (Blakey and Priest, 1980) and from 25% of dried foods such as spices, seasoning mixes, and dried potatoes (Kim and Goepfert, 1971). An outbreak of the long-incubation form was traced to a "meals-on-wheels" program in which food was held at and above room temperature for a prolonged period (Jephcott et al., 1977).

The short-incubation or emetic form of *B. cereus* food poisoning is diagnosed by the isolation of *B. cereus* from the incriminated food. The long-incubation or diarrheal form is diagnosed by isolation of the organism from stool and food. Isolation from stools is not sufficient unless negative stool cultures are obtained from a control group (Terranova and Blake, 1978). Fourteen percent of healthy adults have been reported to have transient gastrointestinal colonization with *B. cereus* (Ghosh, 1978). Serotyping may be of value in identifying a common source but is not readily available. Plasmid analysis recently proved useful in the epidemiological investigation of an outbreak of *B. cereus* gastroenteritis associated with the consumption of beef stew at a nursing home (DeBuono et al., 1988).

Because *B. cereus* gastroenteritis is generally a benign, self-limited illness, antimicrobial agents are of no value in management. Since bacteria grow best at temperatures ranging from 40 to 140°F, infection may be prevented if cold food is refrigerated and if hot food is held at greater than 140°F before serving.

Several methods have been described for production of the diarrheal toxin. Growth of *B. cereus* in brain heart infusion (BHI) broth with 0.1% glucose (pH = 7.4) is simple (Spira and Goepfert, 1972). High speed centrifugation is used to remove organisms and the supernatant is examined serologically by a modified microslide gel double-diffusion method for the identification of *B. cereus* diarrheal antigen (Crowle, 1958). Conditions for production of the emetic toxin are not as well defined. Because of the association of rice-containing foods with the emetic form of *B. cereus* food poisoning, most media for demonstrating emetic activity have contained rice (Melling et al., 1976). Autoclaved rice is soaked in saline. An overnight culture of rice is liquefied by diastase then dialyzed for 24 h at 4°C against 10% polyethylene glycol (Melling et al., 1976). The addition of chicken, beef, or egg proteins or Casamino acids with B vitamins to rice media stimulate the growth of *B. cereus* (Morita and Woodburn, 1977). Serological identification of the emetic antigen has not been possible because of its low molecular weight, so biological assays are used. Rice mixtures containing *B. cereus* emetic toxin fed to monkeys cause emesis in 50% of the animals (Melling et al., 1976). Intravenous injection of kittens with concentrated culture fluids produced by culturing *B. cereus* in BHI broth supplemented with 0.1% glucose (pH = 7.4) and heating at 100°C for 1.5 h has caused emesis (Bennett and Harmon, 1988).

Other *Bacillus* Infections

Other nonanthrax *Bacillus* infections have been classified as 1) local, usually involving the eye or an isolated organ that was previously damaged; 2) deep tissue or mixed, in which a *Bacillus* species is usually found in the company of other organisms; and 3) disseminated, in which the organism is consistently cultured from the blood or cerebrospinal fluid of a seriously ill person (Farrar, 1963).

Local Infections

The eye has been the organ most commonly infected by nonanthrax *Bacillus* species, especially *B. cereus*. They can cause conjunctivitis, keratitis, iridocyclitis, dacryocystitis, orbital abscess, and panophthalmitis. *Bacillus* species are most commonly isolated in the setting of penetrating nonsurgical trauma. In a review of nonsurgical post-traumatic endophthalmitis, *Bacillus* species ranked as the second most common pathogen in five of six series reviewed (Davey and Tauber, 1987). An intra-ocular foreign body such as a metal projectile is often present in this setting or the injury occurs in a rural or farm location where there is a greater risk of contamination with dust or soil. *B. cereus* is one of the most destructive organisms to infect the eye (Davey and Tauber, 1987). Panophthalmitis with *Bacillus* species also occurs in the setting of hematogenous dissemination, as in intravenous drug abusers (Davey and Tauber, 1987; Pearson, 1970; Young et al., 1980).

These patients present with a fulminant endophthalmitis or panophthalmitis that usually results in blindness and the need for enucleation. Although the exact pathogenesis is ill-defined, it is probably related to endogenous infection from contaminated drugs and paraphernalia (Shamsuddin et al., 1982). Approximately 50% of cultures of heroin and drug paraphernalia contain *Bacillus* species, making them the most common organism isolated (Tuazon et al., 1974). In one patient with panophthalmitis, *B. cereus* was isolated from a vitreous aspirate and also from the syringe used for injection (Young et al., 1980). Severe suppurative endogenous panophthalmitis caused by *B. cereus* has also resulted from injection of vitamin B (Bouza et al., 1979) and also after a blood transfusion (Kerkenezov, 1953).

Clinical features are fairly characteristic, with intense pain followed by chemosis, periorbital swelling, and severe proptosis. Within 48 h, a corneal ring abscess develops. This is a hallmark of an intraocular infection with *Bacillus* organisms. The end result is irreversible loss of vision and eventual loss of the eye (Davey and Tauber, 1987; O'Day et al., 1981). A characteristic feature of infection with *B. cereus* is its frequent association with fever and leukocytosis, which are not usually seen in panophthalmitis caused by other bacteria (Davey and Tauber, 1987). Early diagnosis is important. This organism should be considered whenever ocular infection occurs in the setting of penetrating injury with probable soil contamination or in an intravenous drug user. Vitreous aspiration with Gram stain and culture is diagnostic.

Empiric therapy should begin before isolation of an organism and the availability of antibiotic susceptibility data. For treatment of severe ocular infections, early vitrectomy and intravitreal antibiotics, combined with systemic and periocular antibiotics, appear to offer the best chance for success (Davey and Tauber, 1987). Clindamycin or vancomycin should be combined with an aminoglycoside.

The first case of human infection with *B. thuringiensis* was reported by Samples and Buettner (1983) in a healthy farmer who splashed an insecticide containing the organism into his eye. The organism was recovered from a corneal ulcer. The clinical course was much less fulminant than with *B. cereus* infection.

Mixed Infections or Deep-Tissue Infections

This category includes cellulitis, traumatic wound infections, surgical wound infections, infected burns, infected necrotic tumors, necrotizing fasciitis, pyelonephritis, pericarditis, and pneumonia (Bias, 1927; Farrar, 1963; Ihde and Armstrong, 1973; Logan et al., 1985b; Pearson,

1970; Pennington et al., 1976; Tuazon et al., 1979). *Bacillus* species are rare pulmonary pathogens. *B. cereus* has caused pneumonia in patients with malignancy (Bekemeyer and Zimmerman, 1985; Pennington et al., 1976) and in those with no known immune compromise (Jonsson et al., 1983). Cavitating pneumonia has been reported (Leff et al., 1977). *B. sphaericus* caused a large pseudotumor of the lung in a patient with chronic asthma on corticosteroids (Isaacson et al., 1976). Symptoms are indistinguishable from other bacterial pneumonias. Complications include empyema, massive hemoptysis, acute respiratory failure, tension pneumothorax, and bronchopleural fistula (Bekemeyer and Zimmerman, 1985). Cases of necrotizing pneumonia and empyema may require resection of infected lung and decortication (Jonsson et al., 1983).

Bacillus species, especially *B. cereus*, can infect traumatic wounds in both the normal host and the immunocompromised host (Dryden and Kramer, 1987; Jaruratanasirikul et al., 1987). In the immunocompromised patient, the trauma can be as minor as scratch marks exposed to muddy water (Jaruratanasirikul et al., 1987). Severe toxicity may develop when *B. cereus* infects relatively minor burns (Attwood and Evans, 1983). In addition to traumatic wounds, *B. cereus* has infected breast implants (Sliman et al., 1987) and pin sites following pin placement and plaster fixation of an open forearm fracture (Rutala et al., 1986). In the later situation, *B. cereus* was recovered from plaster-impregnated gauze rolls and tapwater samples. The pins may have facilitated infection by serving as a conduit for the plaster-associated bacteria to the pin insertion sites. Plaster samples were subsequently sterilized by steam or gas.

Primary cutaneous *B. cereus* infection was recently reported in neutropenic children (Henrickson et al., 1989). In these cases, there was a spring and summer seasonal predominance but no history or signs of injury to the skin. Vesicles or pustules with rapidly spreading cellulitis were seen only on the extremities. Although neutropenic and febrile, the children were not otherwise systemically ill. Cultures of vesicle fluid or wound drainage yielded pure growth of *B. cereus*. All cases responded to antibiotic therapy. Cutaneous *B. cereus* infection is clinically similar to cutaneous anthrax and has the same seasonality. This entity may be related to the secretion of the same or similar exotoxins.

Necrotizing fasciitis caused by *Bacillus* species has been reported in a leukemic patient and in a patient with sickle cell disease (Sliman et al., 1987; Tuazon et al., 1979). In both cases, *Bacillus* species grew in pure culture from deep tissue. *B. cereus* has been associated with myonecrosis postoperatively (Fitzpatrick et al., 1979) and fol-

lowing trauma (Johnson et al., 1984; Groschel et al., 1976). Treatment of these deep soft tissue infections requires surgical debridement and systemic antibiotics. Amputation may be necessary.

Streptococcal and other organisms are frequently isolated along with the *Bacillus* species. It is frequently unclear what role the *Bacillus* plays in these mixed infections. It may be a copathogen, a secondary invader, or a colonizer. Ihde and Armstrong (1973) found that whether the *Bacillus* was treated did not affect outcome in surgical wounds. However, they did note a change in the character of the drainage from sanguinous to serous after the *Bacillus* was no longer recovered in culture.

Disseminated Infections

The category of disseminated infections includes bacteremia, endocarditis, meningitis, and other such infections. Since *Bacillus* species are ubiquitous in the environment, it is not suprising that positive cultures for these organisms are fairly common. They are only rarely associated with actual infection, however. The prevalence of positive blood cultures for *Bacillus* species has ranged from 0.1 to 0.9% (Dalton and Allison, 1967; Kotin, 1952; Pearson, 1970). Isolation of *Bacillus* species from blood is clinically significant in 5 to 10% of cases (Weber et al., 1989).

Bacteremia is relatively common in *Bacillus* infections and the incidence is increasing. *B. cereus* is the predominant species. Bacteremia can be a complication of indwelling intravascular catheters (Banerjee et al., 1988; Cotton et al., 1987; Sliman et al., 1987). Scanning and transmission electron microscopy of a Hickman catheter after removal showed *Bacillus* organisms embedded in a biofilm composed of Gram-positive cocci and glycocalyx (Banerjee et al., 1988). In a study by Sliman et al. 1987, an intravascular device proved to be the source of the bacteremia in one-half of the cases, as evidenced by a positive culture of purulent drainage from a peripheral vein or the recovery of greater than 15 colonies from a semiquantitative culture of a catheter tip. Isolated bacteremias are usually eradicated easily. Bacteremia may clear after removal of an intravascular device in the absence of specific antibacterial therapy (Sliman et al., 1987). For *Bacillus* bacteremias in immunocompromised patients (especially those who are neutropenic) the catheter should be removed and systemic antibiotics administered (Banerjee et al., 1988; Cotton et al., 1987).

Bacteremia has also occurred in association with infections in a variety of body sites. Unlike those with primary bacteremia, patients with infections of solid organs frequently have high morbidity. Some of these cases of bacteremia may actually have been cases of endocarditis, and some were treated as such. A relatively common situation has been pneumonia with bacteremia in individuals with acute leukemia and neutropenia (Coonrod et al., 1971a; Ihde and Armstrong, 1973; Pennington et al., 1976; Sathmary, 1958). The neutropenic patient is at risk for life-threatening bacteremia following seemingly minor trauma (Guiot et al., 1986).

An outbreak of five cases of bacteremia occurred in a group of hemodialysis patients exposed to contaminated dialysis fluid and equipment (Curtis et al., 1967). Individual cases of bacteremia in association with volvulus and peritonitis (Sugar and McCloskey, 1977), infected ventriculojugular shunt cured only by removal of the shunt (Cox et al., 1959), and sepsis in a newborn infant, perhaps related to contaminated blood transfusion (Yow et al., 1949), have been reported.

There have been five outbreaks of pseudobacteremia associated with contaminated broth culture media (Crowley et al., 1983; Noble and Reeves, 1974), contaminated syringes (MacDonald, 1982) or alcohol swabs (Berger, 1983), and a contaminated needle in a radiometric blood culture analyzer (Gurevich et al., 1984).

Endocarditis due to *Bacillus* organisms is uncommon; only about 12 cases have been reported in the English-language literature (Agarwala et al., 1975; Block et al., 1978; Farrar, 1963; Oster and Kong, 1982; Yeh et al., 1967). More than one-half the cases have occurred in intravenous drug users (Craig et al., 1974; Reller, 1973; Tuazon et al., 1979; Weller et al., 1979), probably related to the frequent presence of *Bacillus* organisms on injection paraphernalia and in street heroin (Tuazon et al., 1974). *Bacillus* endocarditis cannot be distinguished from other bacterial causes of endocarditis on the basis of clinical features. The majority of patients have had low-grade fever and heart murmurs. There is a predominance of tricuspid valve involvement. Some have had hepatosplenomegaly, and a few have had peripheral stigmata. *B. cereus* has caused infection of a permanent ventricular pacemaker (Sliman et al., 1987). Echocardiogram revealed a vegetation on the pacemaker wire in the right ventricle. The organism was isolated from blood, the subcutaneous pacemaker pouch, and right ventricular tissue. There was persistence of the organism despite 10 days of appropriate antibiotic therapy. Cure was achieved only after removal of the pacemaker and 4 weeks of antibiotic therapy postoperatively.

In a study of 849 cerebrospinal fluid (CSF) cultures, nine were positive for nonanthrax *Bacillus* species. In seven patients the isolates represented contamination (Feder et al., 1988).

There has been at least one outbreak of pseudo-meningitis caused by contamination of broth culture media by *Bacillus* species (Lettau et al., 1988). True meningitis due to *Bacillus* organisms has been reported primarily in situations in which there is either direct access of exogenous organisms to the subarachnoid space (spinal anesthesia, head trauma, and neurosurgical procedures with and without foreign bodies), or in individuals whose immune function is depressed (newborn state, alcoholism, and hematologic malignancy), although at least one case has been reported in an otherwise healthy individual (Allen and Wilkinson, 1969; Boyette and Rights, 1952; Colpin et al., 1981; Farrar, 1963; Park et al., 1976; Patrick et al., 1989; Weinstein and Colburn, 1950; Weidermann, 1987). It has also occurred secondary to other infections such as otitis, mastoiditis, infected subdural hematoma, and hematogenous dissemination from a urinary tract infection. Causative organisms have included *B. alvei*, *B. megaterium*, *B. subtilis*, *B. pumilus*, *B. circulans*, *B. sphaericus*, and *B. cereus*. Single cases of postoperative ventriculitis due to *B. licheniformis* and *B. cereus* have been reported (Young et al., 1982). The latter infection was in a patient with a ventriculoperitoneal shunt. Removal of any foreign body is essential for cure.

Brain abscess with *B. cereus* has been reported rarely (Ihde and Armstrong, 1973; Jenson et al., 1989). All of the patients were immunocompromised. In two of the patients, involvement of the brain parenchyma was probably via the hematogenous route from primary foci of *B. cereus* pneumonia (Ihde and Armstrong, 1973). Diagnosis was made postmortem. The other patient had multiple brain abscesses, concurrent meningitis and may have acquired the infection hematogenously from a potentially contaminated transfusion (Jenson et al., 1989). He was successfully treated with vancomycin and gentamicin, and vancomycin and rifampin for a total of 8 weeks. Mild memory deficit and mild residual paresis of the right upper extremity persisted as sequelae of the infection.

Acute and chronic osteomyelitis and septic arthritis caused by *Bacillus* species are rare. In a review of *Bacillus* infections, 10 cases of bone and joint infection were reported (Pearson, 1970). The organism was present in mixed culture in 9 of the 10 cases, and in 5 it was obtained from a wound or drainage. Most of the patients had previous trauma. Acute vertebral osteomyelitis caused by *B. cereus* has been reported in an intravenous drug user (Tuazon et al., 1979). An association between *Bacillus* species osteomyelitis and sickle cell disease has been noted (Reboli et al., 1989; Sliman et al., 1987; Solny et al., 1977). *B. alvei* caused infection of a prosthetic hip in a patient with sickle cell disease, probably via the hematogenous route (Reboli et al., 1989). In general, bacteremia in the setting of osteomyelitis is rare. *B. cereus* septic arthritis has occurred as a complication of arthrography (Robinson, 1979). *Bacillus* infections of bone and joints have been difficult to eradicate, require multiple surgical procedures, and cause substantial morbidity (Sliman et al., 1987).

Except for the characteristic signs and symptoms of panophthalmitis, most infections due to nonanthrax *Bacillus* species do not have distinctive clinical presentations, and although serious infections are being recognized with increasing frequency, endocarditis, meningitis, and sepsis are still sufficiently rare that the question of contaminant vs. pathogen is still valid. Diagnosis of true infection rests on the isolation of the organism from blood, normally sterile body fluids, or closed spaces (such as the pleural space) of a susceptible host in the appropriate clinical setting. A positive Gram stain and growth in pure culture are contributory evidence of the *Bacillus* being a true pathogen, whereas growth only in thioglycolate broth (indicating a small number of organisms) or the presence of *Bacillus* organisms in mixed culture with other species is suggestive of a contaminant. Although infection can occur in healthy persons, it is most often seen in immunocompromised patients such as those with hematologic malignancies, intravenous drug users, or patients with severe trauma (Ihde and Armstrong, 1973; Pennington et al., 1976; Tuazon et al., 1979).

Hypersensitivity Reactions

Allergic reactions have been described in workers exposed to autolysates of *B. subtilis* used as enzymes in laundry products (Dubos, 1971; Flindt, 1969; Greenberg et al., 1970; Pepys et al., 1969). These reactions were mainly dermatitis and asthma. Those involved showed immediate and late reactions to inhalation and skin prick tests (Flindt, 1969). Hypersensitivity pneumonitis following exposure to wood dust contaminated with *B. subtilis* has been described (Johnson et al., 1980.)

Treatment and Prognosis

Many strains of *Bacillus* species are susceptible to the aminoglycosides, tetracycline, chloramphenicol, erythromycin, vancomycin, and clindamycin (Coonrod et al., 1971b; Tuazon et al., 1979). Susceptibility to penicillin, ampicillin, methicillin, and cephalosporins is usually species related and has been shown to be high for *B. subtilis* and low for *B. cereus*. *B. pumilus* is intermediate between *B. subtilis* and *B. cereus*. *B.*

cereus is the most resistant species, showing resistance to the penicillins and cephalosporins that may be attributable to its ability to produce a β-lactamase that hydrolyzes these agents (Sabath and Abraham, 1965). In vitro susceptibility tests reveal all *B. cereus* strains to be susceptible to imipenem, vancomycin, chloramphenicol, gentamicin, and ciprofloxacin (Weber et al., 1988). Non-*B. cereus* strains were most susceptible to imipenem, vancomycin, daptomycin, and ciprofloxacin (Weber et al., 1988). Further studies are needed before imipenem and ciprofloxacin can be recommended for treatment of *Bacillus* infections. Clindamycin or vancomycin with or without an aminoglycoside may be the treatment of choice for endocarditis or sepsis with *B. cereus* (Sliman et al., 1987; Tuazon et al., 1979). Other species can be treated with penicillins or cephalosporins if they are found to be susceptible. Surgical drainage may be necessary in closed space and soft tissue infections. Infected prosthetic heart valves may need replacement but infected native valves usually can be treated with antibiotics alone.

Morbidity and mortality for disseminated infections were high prior to the antibiotic era. Except for panophthalmitis, which usually results in loss of vision and of the eye, other infections by *Bacillus* species have a good prognosis unless the underlying disease (such as malignancy) supervenes. *B. cereus* endocarditis in intravenous drug users has a relatively benign course and favorable prognosis. Of patients with meningitis, approximately 40% survived; however, most have had central nervous system sequelae.

Pathology and Pathogenesis

The pathologic changes in organs infected by nonanthrax *Bacillus* species are the inflammatory reactions caused by bacteria in general. There have not been any special or pathognomonic changes described in humans. Subcutaneous injection of *B. cereus* in mice, guinea pigs, and rabbits has caused deep, hemorrhagic, ulcerative skin lesions and death (Burdon et al., 1967). Direct cytotoxicity of *B. cereus* culture filtrate for tissue culture cells has been noted (Bonventre, 1965). *B. cereus* culture filtrates were noted to kill mice and rats within minutes after intravenous injection (Bonventre and Eckert, 1963). Pathologically there were widespread thromboses. The filtrates were noted to be hemolytic and dermonecrotic. The pathologic changes included focal areas of coagulative necrosis and inflammatory cells in the pulmonary arterioles and capillaries. Thrombi were found in the pulmonary vessels. Because no organisms were seen in tissue sections, toxins were believed to be responsible for illness and death. This hypothesis was further supported by the finding that antitoxic serum had a protective effect.

In one case of neonatal meningitis, postmortem histopathologic examination revealed an invasive disease involving the brain parenchyma. The cellular composition of the CSF was significant for an increased number of mononuclear cells, implying a chronic infection (Patrick et al., 1989). The invasive and destructive nature of *B. cereus* has been demonstrated by microscopic examination of brain tissue in a patient with multiple brain abscesses (Jenson et al., 1989). There was extensive bacterial invasion of brain tissue and hemorrhagic necrosis. Localized tissue infection with *B. cereus* is usually necrotizing due to the production of a potent exotoxin and usually results in rapid, fulminant tissue destruction.

Different *Bacillus* species produce a variety of enzymes including amylase, collagenase, hemolysin, lecithinase, phospholipase, protease and urease, antimicrobial substances (bacitracin, gramicidin, polymyxin, and tyrocidine), pigments, and toxins (Williams, 1981). *B. cereus* produces distinct extracellular products: β-lactamases, hemolysins, phospholipase C, and two lethal toxins (Coolbaugh and Williams, 1978; Gilbert and Kramer, 1984; Thompson et al., 1984; Turnbull et al., 1979a; Turnbull, 1981). The lethal toxins may contribute to the virulence of *B. cereus*. One has a molecular weight of approximately 50,000 and is a "loop fluid-inducing/skin test/necrotic toxin." The other toxin has a molecular weight of 55,000 to 56,000 and is cereolysin. It interacts with cholesterol as a receptor in the host cell membrane. It demonstrates vascular permeability activity which is difficult to distinguish from that of "loop fluid-inducing/skin test/necrotic toxin." Two hemolysins have been described. One has a molecular weight of 52,000 and causes immediate lysis of red blood cells (Coolbaugh and Williams, 1978). The other has a molecular weight of 31,000. *B. cereus* is not the only species that produces hemolysins; at least 18 *Bacillus* species have the capability (Bernheimer and Grushoff, 1967).

The lysins of some species resemble streptolysin O. Paper chromatography has demonstrated that hemolysins are not the same as phospholipases (Stein and Logan, 1965). Phospholipases and lecithinases may be identical, however. Phosphatidyl-choline hydrolase is also known as phospholipase C. It may have a role in ocular infections by disrupting cell membrane phospholipids after they have been exposed by the action of other toxins (Turnbull, 1981). Hemolysins may be responsible for changes in quality of drainage from infected wounds (Ihde and Armstrong, 1973).

Specimen Collection, Transport, Maintenance, and Microscopic Examination

Specimens and cultures which may contain *B. anthracis* require specific laboratory safety precautions. All work should be performed in a biological safety hood since aerosolization may carry a risk of infection by inhalation. Personnel should wear gloves while processing specimens and performing tests. Bench space should be disinfected with 1% sodium hypochlorite after work is completed and contaminated items should be autoclaved prior to disposal.

Vesicular fluid or exudate from cutaneous lesions suspected of being infected with *B. anthracis* should be sampled using dry sterile swabs (Doyle et al., 1985). Blood cultures should be taken and specimens of lymph nodes, spleen, peritoneal exudate, or other tissues obtained by biopsy or necropsy should be obtained for microscopic examination and culture. Specimens should be placed in secure sterile containers for transportation to the laboratory. The swabs can be used for inoculation of media for cultivation of the organism and for preparation of smears. Smears should be fixed for 3 to 5 min in Zenker's solution (2.5% aqueous potassium bichromate and 8% mercuric chloride) or 10% Formalin (37% formaldehyde) for 10 min to ensure inactivation of spores; even repeated passage of the slide through a flame may not kill all spores. Smears can be stained with either Gram or Giemsa stain. Microscopically, *B. anthracis* appears as a large Gram-positive rod with square ends, 1.0 to 1.3 μm wide and 3 to 10 μm long. Spores when present are oval, located centrally or subterminally, and produce little or no swelling of the cell. Capsules may often be seen in direct smears from infected tissues using capsule-staining methods, and specific fluorescent monoclonal antibody reagents may be obtained from the CDC, Atlanta, GA.

Clinical specimens such as blood, cerebrospinal fluid, and wound exudates for isolation of other *Bacillus* species do not require special handling. Prompt plating to prevent growth of contaminants is necessary. Tissue specimens should be macerated and inoculated into a peptone broth. As spores are viable for long periods, maintenance of cultures after initial isolation is usually not difficult. Preservation in sterile soil has been suggested, but nutrient agar with manganese sulfate is equally good for sporulation and maintenance and is more convenient than soil extract (Norris et al., 1981). *Bacillus* species may be stored on agar slants, frozen at −70°C, or freeze-dried for long-term maintenance. Repeated freezing and thawing should be avoided. Freeze-drying may alter the character of the organisms as can repeated subculturing at frequent intervals.

In cases of *B. cereus* food poisoning, food stuffs to be examined should be kept at or near 5°C until examined. They can be stored in a refrigerator for up to 48 h. If they are to be stored for longer periods of time they should be frozen. Twenty-five-gram portions of food are homogenized in Butterfield's buffer in a blender and diluted before testing (Bennett and Harmon, 1988).

Isolation and Identification

Cells of *Bacillus* organisms range from approximately 0.4 to 2 μm in width and from 3 to 12 μm in length. They are straight or slightly curved and have round or square ends. An initial Gram stain should be done on any suitable clinical material. It is the most rapid and easiest way to assess the quality of the sample and to have a preliminary categorization of the pathogen. If Gram-positive bacilli are seen, further testing will be needed to distinguish *Bacillus* species from other Gram-positive rods such as *Kurthia*, *Listeria*, *Rothia*, *Corynebacterium*, *Erysipelothrix*, and *Clostridium*. *Bacillus* species may at times resemble Gram-negative bacilli, especially cells from colonies that are older. In contrast to the nonfermenting Gram-negative rods, most *Bacillus* species do not usually grow on enteric agars. In addition, *Bacillus* species are susceptible to vancomycin, whereas Gram-negative nonfermenters are not, and a KOH test can be performed in which Gram-negative rods show a viscous thread (Gregersen, 1978). A colony is stirred into one or two drops of 3% KOH on a glass slide with a loop and the loop is slowly raised. Gram-negative bacteria make the KOH viscous, and a thread of this material follows the loop for 0.5 to 2 cm or more. Some *Bacillus* strains, particularly cells from older cultures that have lost their Gram positivity, may give a Gram-negative-type reaction; this test is of value for identification of *Bacillus* species only if no viscous thread is formed.

B. anthracis produces large, raised, opaque, grayish, granular colonies within 24 h when grown on ordinary laboratory media at 37°C. The borders of the colonies are irregular and may resemble a "Medusa head" or "comet tails." The cells adhere tenaciously to one another and if material is picked from the colony with an inoculating needle the remainder of the colony may assume a "stalagmite" shape.

Doyle et al. (1985) have provided a general approach for the identification of *B. anthracis*. In order of importance, they recommend seven procedures:

1. Culture the specimen on sheep blood agar. If the specimen is heavily contaminated use the selective PLET medium of Knisely, which contains polymyxin, lysozyme, EDTA, and thallous acetate. Each batch of this medium should be tested to demonstrate that it will allow growth of known strains of *B. anthracis*, while inhibiting growth of *B. cereus*.

2. Subculture the isolate on nutrient agar or BHI agar containing 0.5% sodium bicarbonate and supplemented with 0.7% bovine serum albumin, and incubated in 5% CO_2. Demonstrate the presence of a capsule by using either M'Fadyean stain or fluorescein-labelled anti-poly-D-glutamic acid. Fluorescent-antibody reagent may be used to detect organisms in tissue sections or from blood smears or culture. Fluorescein conjugates of heterologous sera and monoclonal antibody to capsule can be obtained from the CDC, Atlanta.

3. Determine the toxin-antitoxin reaction using a double diffusion assay with R-medium plus 1.5% agar (Ristroph and Ivins, 1983). A positive reaction confirms identification of *B. anthracis* but a negative reaction does not exclude it.

4. Test for susceptibility to penicillin; *B. anthracis* is the only *Bacillus* species which is consistently susceptible to penicillin G.

5. Determine the rates of hydrolysis of p-nitro-phenyl-α-D-glucopyranoside and p-nitro-phenyl-α-D-maltoside in the presence and absence of 1% Triton X-100. Alpha-glucosidase activity is increased in *B. anthracis* by incubation in the detergent; glucosidase activity in other members of the *B. cereus* group is diminished.

6. Test for agglutination of cells by soybean *(Glycine max)* lectin but not by the snail *Helix pomatia* lectin.

7. Determine susceptibility to gamma phage (Doyle et al., 1985; Rees et al., 1988).

The "string of pearls" test is based upon the susceptibility of *B. anthracis* to penicillin (Rees et al., 1988). A drop of young (12–18 h) broth culture is placed on two plates of nutrient agar that contains either 0.5 or 10 units of penicillin per milliliter. After incubating the inoculated media at 37° for 3 to 6 h, a cover slip is placed directly on the growth present on the medium. Microscopic examination of the underlying growth under low magnification reveals the presence of large rounded cells (or a "string of pearls"). Little or no growth should be seen on the medium containing 10 units of penicillin per milliliter. Approximately 95% of strains of *B. anthracis* give a positive test; only 8% of non-anthrax *Bacillus* strains are positive.

It is fairly easy to differentiate between *B. anthracis* and other *Bacillus* species with the exception of *B. cereus*. Table 1 shows important differential characteristics between *B. anthracis* and other pseudoanthrax bacilli. Unlike *B. anthracis*, *B. cereus* is usually resistant to penicillin, is resistent to gamma phage, does not encapsulate on bicarbonate agar, and does not show fluorescence of cell wall and capsule on fluorescent antibody-stained smears.

Bacillus cereus is a large-celled member of group 1. It has a cell width greater than 0.9 μm and spores which do not appreciably swell the sporangium. It is controversial whether *B. anthracis*, *B. mycoides*, and *B. thuringiensis* should have species status or be considered variant species of *B. cereus*. Within this species, strain heterogeneity is relatively common but typical characteristics are very stable. Four

Table 1. Differences between *Bacillus anthracis* and the pseudoanthrax bacilli.

B. anthracis	Anthrax-like or pseudoanthrax bacilli
Nonmotile	Generally motile[a]
Capsulated	Noncapsulated[a]
Grows in long chains	Grow in short chains
No turbidity or pellicle in broth	Often turbidity and pellicle in broth
No growth on penicillin agar (10μg/ml)	Usually good growth on penicillin agar
Inverted fir-tree growth in gelatin	Fir-tree growth absent or atypical[a]
Methylene blue reduced weakly	Methylene blue usually reduced strongly
Hemolysis of sheep cells weak	Hemolysis of sheep cells often strong
Liquefaction of gelatin slow	Liquefaction of gelatin usually rapid[a]
Lecithinase reaction weakly positive	Lecithinase reaction strongly positive[a]
Ferments salicin slowly	Often ferment salicin rapidly
Polysaccharide precipitin reaction strongly positive	Polysaccharide precipitin reaction weakly positive
Produces toxin, neutralized by *B. anthracis* antitoxin	Any toxic substances produced not neutralized by *B anthracis* antitoxin
Pathogenic to laboratory animals	Mostly nonpathogenic. If pathogenic, produce disease unlike anthrax
Susceptible to phage	Insusceptible to phage
Culture filtrates nontoxic to tissue culture cells	Culture filtrates toxic to tissue culture cells[a]

[a]For *B. cereus*. From Reboli and Farrar (1988).

characteristics are useful in differentiating members of the *B. cereus* group (hemolytic activity, motility, rhizoid growth, and detection of toxin crystals) (Harmon, 1982).

Hemolytic Activity

Tryptic-soy-sheep blood agar is inoculated by lightly touching the agar surface with a loopful of culture. The plate is incubated at 30°C for 24 h and observed for hemolytic activity as indicated by a zone of complete hemolysis around the growth. *B. anthracis* is nonhemolytic; *B. cereus* is strongly hemolytic. *B. mycoides* and *B. thuringiensis* are weakly hemolytic or produce hemolysis only under the growth.

Motility Tests

Motility may be determined by direct microscopic examination or by using semisolid *B. cereus* motility medium (Harmon, 1982). The medium is inoculated by stabbing down the center and is incubated at 30°C for 18 to 24 h. Motile strains produce diffuse growth into the medium away from the stab; nonmotile strains except for *B. mycoides* grow only in and along the stab. Questionable results should be confirmed by the microscopic motility test which is performed by adding 0.2 ml of sterile distilled water to a nutrient agar slant, inoculating the slant with a loopful of culture, and incubating at 30°C for 6 to 8 h. A loopful of liquid culture from the base of the slant is suspended in a drop of water on a clean slide, covered with a cover slip, and examined immediately for motility (Bennett and Harmon, 1988). *B. cereus* and *B. thuringiensis* are motile; *B. anthracis* and the rhizoid strains of *B. mycoides* are nonmotile.

Rhizoid Growth

A pre-dried nutrient agar plate is inoculated centrally and incubated at 30°C for 1 to 2 days. If the culture is rhizoid, root-like structures will develop up to several centimeters from the point of inoculation. Rhizoid growth is characteristic only of *B. mycoides*.

Detection of Toxin Crystals

Endotoxin crystals of *B. thuringiensis* may be detected by phase contrast microscopy or by staining with 0.5% aqueous basic fuchsin or TB carbol fuchsin. The other members of the *B. cereus* group do not produce endotoxin crystals that can be detected by staining.

In certain clinical situations in which *Bacillus* infection is suspected, specimens can be suspended in distilled water or nonnutrient buffer

and pasteurized (heated at 70–80°C for approximately 10 min) to kill contaminating vegetative cells. Spores will survive. Caution is needed, however, as organisms may be present only in the vegetative state and no growth will be achieved. In addition, heat treatment of spores may cause mutations. Air-drying and treatment with 50% ethanol for 1 h are also effective for selecting out sporulating organisms. Treatment with ethanol may be more desirable. Sporulation is often stimulated on esculin agar and may be facilitated on an acidified medium such as triple sugar iron agar (TSI).

Isolation is relatively easy, as most medically important *Bacillus* species grow well on blood agar or simple nutrient agar, which is composed of a meat extract in peptone with a pH of 6.8 to 7.0. Growth is sometimes improved by glucose but not by serum. Cultures should be incubated aerobically at 35 to 37°C for 24 h. Some strains require enrichment techniques using specific broth, incubation under specific conditions of pH, temperature, and salt concentration, or plating on specific agar media. Colony morphology and microscopic appearance form the basis of preliminary identification.

Nutrient Agar (pH = 6.8–7.0)

Agar	15.0 g
Peptone	5.0 g
Meat extract	3.0 g
Distilled water	To 1 liter

For sporulation, add 5 mg of hydrous manganese sulfate per 1 liter of medium.

Nutrient Broth (pH = 6.8)

Peptone	5.0 g
Meat extract	3.0 g
Distilled water	To 1 liter

Colony morphology should be observed from young (18–24 h) cultures grown on nutrient agar under aerobic conditions. Single colonies are usually two to several mm in diameter and may have a finely granular appearance. Other colonies appear membranous and wrinkled (Wilson, 1983). *B. cereus* colonies vary from small, shiny, and compact to large, feathery, and spreading. On sheep blood agar, a lavender-colored colony with beta hemolysis is seen. Colonies of *B. subtilis* are usually large, dull, and flat, with a ground glass appearance. The microscopic appearance of cells is best observed on slides freshly coated with a thin layer of 2% water agar and examined with a phase-contrast microscope (Claus and Berkeley, 1986). Colonies suspected of being *B. cereus* should be subcultured and checked for motility, hemolysis, and susceptibility to penicillin. Serotyping with antibody directed against flagellar antigens should be employed for confirmation of *B. cereus*.

Four selective and differential plating media have been described for the isolation of *B. cereus* (Holbrook and Anderson, 1980; Kim and Goepfert, 1971; Mossell et al., 1967; Szabo et al., 1984). Three of them contain mannitol to enhance differentiation. The most common procedure for isolation and presumptive identification of *B. cereus* is based on the egg yolk reaction (Doyle et al., 1985). In this reaction, turbidity develops in egg yolk or in agar that contains egg yolk. It is caused by an extracellular substance (or substances) referred to as egg yolk turbidity factor, lecithinase, or phospholipase. The reaction may be due to a more complex series of events than the action of a single enzyme (Kushner, 1957). Material to be cultured is placed onto blood agar (Harmon et al., 1984; Schiemann, 1978) containing polymyxin to suppress Gram-negative growth. Plates are incubated at 37°C overnight, and suspect colonies are then inoculated onto mannitol egg yolk agar by stabbing various sites on the plate and incubated at 35 to 37°C overnight. As *B. cereus* is lecithinase positive and does not ferment mannitol, plates are examined for a zone of precipitation or halos around sites of inoculation and for lack of evidence of fermentation. (If fermentation has occurred, the background color changes from violet to yellow.) Similar reactions may be seen with other members of the *B. cereus* group (*B. anthracis*, *B. thuringiensis*, and *B. mycoides*). Some strains of *B. cereus* give a weak or negative egg yolk reaction. On polymyxin pyruvate-egg-yolk-mannitol-bromothymol blue-agar (PEMBA) media, *B. cereus* has a distinct colonial appearance (Holbrook and Anderson, 1980). After incubation at 37°C for 24 to 48 h, colonies of *B. cereus* are rough, dry, and crenated or rhizoid. They have a distinctive bright blue color. (*B. thuringiensis* has the same appearance).

Egg-Yolk Reaction Medium

Tryptone	10 g
Disodium hydrogen phosphate	5 g
Potassium dihydrogen phosphate	1 g
Sodium chloride	2 g
Magnesium sulfate	0.1 g
Glucose	2 g
Distilled water	To 1 liter

Egg yolk (1.5 ml) is added to 100 ml of basal medium. The medium is held refrigerated overnight and the supernatant broth is aliquoted.

Measuring the Egg-Yolk Reaction
Cultures are inoculated into egg-yolk broth and into a control broth without egg yolk. After incubation for 1, 3, 5, and 7 days observe for the appearance of a heavy white precipitate in or on the surface of the egg-yolk medium.

PEMBA (Oxoid) (pH = 7.2) (Holbrook and Anderson, 1980)

Agar	18.0 g
Peptone	1.0 g
D-Mannitol	10.0 g
$MgSO_4$	0.1 g
NaCl	2.0 g
Na_2HPO_4	2.5 g
KH_2PO_4	0.25 g
Bromothymol blue	0.12 g
Distilled water	To 1 liter

Prior to use, the following are added to 90-ml aliquots of the basal medium:

20% (w/v) Sodium pyruvate	5 ml
Polymyxin	100 units/ml
Egg-yolk emulsion (Oxoid)	5 ml

Surface plating is usually employed to determine the presence of *B. cereus* in outbreak foods. The official method of the Association of Official Analytical Chemists (AOAC) for enumerating *B. cereus* in foods uses mannitol-egg yolk-polymyxin (MYP) media (Lancette and Harmon, 1980). Blood agar, PEMBA, and KG agar (Kim and Goepfert, 1971) are of similar efficacy and are used in some laboratories. If *B. cereus* counts are expected to be less than 1,000 per gram, the alternative AOAC most probable number (MPN) method using tryptic-soy-polymyxin broth is recommended (Lancette and Harmon, 1980). Presumptive colonies from the above plating media should be transferred to nutrient agar slants and subjected to biochemical tests.

The nature of members of this genus is such that strains may not exhibit the important characteristics of the genus, let alone the species. Because of the number of species and variant strains, it may not be possible to speciate quickly. Norris et al. (1981) suggest basing species identification on the results of two morphologic features, width of the rod, and parasporal body in the sporangium, and 11 tests: catalase production, Voges-Proskauer reaction, pH in Voges-Proskauer broth, growth in anaerobic agar, growth at 50°C, growth at 65°C, growth in 7% sodium chloride, production of acid and gas from glucose, reduction of nitrate to nitrite, hydrolysis of starch, and casein decomposition. Citrate utilization may not be useful because of disagreement in interpretation. Wilson (1983) advocates also testing for gelatin liquefaction, urease production, and growth in 4% sodium chloride. A scheme for identification of *Bacillus* species is provided in Table 2. Media recipes and performance of tests are based on the work of Gordon et al. (1973) and Smith et al. (1952).

Catalase Test

Cultures grown for 24 to 48 h on nutrient agar slants are flooded with 0.5 ml of 10% hydrogen peroxide. The reaction is positive if there is a rapid bubbling of gas. If

[a]+, greater than 85% of strains positive; −, greater than 85% of strains negative; V = variable character; ND, no data available.
From Reboli and Farrar (1988).

no gas bubbles form, repeat, using growth on chocolate agar. The test is not for cultures grown on blood agar because of the catalase present in the red blood cells. It can be done on egg-yolk agar.

Voges-Proskauer Test Broth (pH = 6.5)

Proteose peptone	7 g
Glucose	5 g
Sodium chloride	5 g
Distilled water	To 1 liter

J broth for V-P Reaction (pH = 7.3–7.5)

Tryptone	5 g
Yeast extract	15 g
Distilled water	To 1 liter

Add aseptically glucose 5 g/liter sterilized separately.

V-P Reaction (Acetyl methyl carbinol production)

Tubes of V-P broth should be inoculated in triplicate and tested for acetyl-methyl-carbinol production after incubation for up to 7 days. Mix 3 ml of 40% (w/v) sodium hydroxide with the culture and add 0.5 to 1 mg of creatine. Observe for the production of a red color after 30 to 60 min at room temperature. Fastidious insect pathogens should be grown on J-broth medium. For pH testing, before cultures incubated for 7 days are tested for acetyl-methyl carbinol, the pH is measured.

Anaerobic Agar (pH = 7.2)

Trypticase	20 g
Glucose	10 g
Sodium chloride	5 g
Agar	15 g
Sodium thioglycolate	2 g
Sodium formaldehyde sulfoxylate	1 g
Distilled water	To 1 liter

Inoculate a tube of anaerobic agar with a small loopful of nutrient broth culture by stabbing to the bottom of the culture tube. At incubation temperatures below 45°C the growth should be recorded at 3 and 7 days.

Growth in Sodium Chloride

Tubes of nutrient broth containing 0, 4, 7, and 10% (w/v) sodium chloride are inoculated and incubated. Observe for growth during up to 14 days of incubation.

Nitrate Reduction Broth (pH = 7.0)

Peptone	5 g
Meat extract	3 g
Potassium nitrate	1 g
Distilled water	To 1 liter

Reduction of nitrate to nitrite

Grow cultures in the above broth. After 3 and 7 days incubation, test by moistening a strip of potassium iodide/starch paper with a few drops of 1 N HC 1 and then touching the paper with a loopful of the culture. Observe for the production of a purple color indicating the presence of nitrite and for the accumulation of nitrogen gas. For a more rapid test, nitrate broth is inoculated and incubated at 35°C for 24 h. Sulfanilic acid and alpha-naphthol (0.25 ml each) are added. The presence of nitrite is indicated by an orange color that develops within 10 min.

Starch Hydrolysis Agar

Potato starch	1 g/10 ml cold distilled water
Nutrient agar	100 ml

Starch Hydrolysis Test

Inoculate duplicate plates of starch agar and incubate. At 3 and 5 days, flood one of the plates with 95% ethanol. After 15 to 30 min the unchanged starch will become white and opaque. Observe for a clear zone underneath and around the growth as an indicator of hydrolysis.

Casein Decomposition; Milk Agar

Agar	1 g in 50 ml of distilled water
Skim milk powder	5 g in 50 ml of distilled water

Casein Decomposition Test

Inoculate plates of milk agar with one streak of inoculum and examine after incubation at 7 and 14 days for clearing of the casein around and underneath the growth.

Citrate Utilization; Medium (pH = 6.8)

Trisodium citrate	1 g
Magnesium sulfate	1.2 g
Diammonium hydrogen phosphate	0.5 g
Potassium chloride	1 g
Agar	15 g
Distilled water	920 ml
Phenol red (0.04% w/v)	20 ml
Trace element solution*	40 ml

*$FeSO_4$, 200 mg; $ZnSO_4$, 10 mg; $MnCl_2$, 3 mg; H_3BO_3, 30 mg; $CoCl_2$, 20 mg; $CuCl_2$, 1 mg; $NiCl_2$, 2 mg; Na_2MoO_4, 3 mg; ethylene diamine tetraacetate, 500 mg; distilled water, 1 liter.

Citrate Utilization Reaction

Inoculate slants of citrate medium and incubate up to 14 days. Observe for production of a red (alkaline) color indicating utilization of organic acids.

Gelatin Liquefaction; Nutrient gelatin (pH = 7.0)

Use commercial nutrient gelatin medium or plain gelatin.

Gelatin	120 g
Distilled water	1 liter

As an alternative, nutrient agar supplemented with 0.4% gelatin may be used.

Gelatin Liquefaction Test

Inoculate tubes of nutrient gelatin and incubate at 28°C. Observe for liquefaction at 3 to 4 day intervals for 4 weeks. Before examination, hold the tubes at 20°C for about 4 h to allow unchanged gelatin to harden. If the gelatin does not harden at 20°C, liquefaction has occurred.

Lysozyme Resistance; Medium

Nutrient broth	99 ml
Lysozyme solution	1 ml

(10,000 enzyme units/ml of distilled water)

Lysozyme Test

Inoculate a loopful of a broth culture into a tube of the above medium and into a control tube of nutrient broth. After incubation for up to 7 to 14 days observe for growth or its absence. Members of the *B. cereus* group are resistant to lysozyme.

Tyrosine Decomposition; Agar

L-Tyrosine	0.5 g
Distilled water	10 ml
Sterile nutrient agar	100 ml

Tyrosine Test

Inoculate plates of the above agar with one streak of inoculum and incubate. Observe at up to 21 days for clearing of the tyrosine crystals around and below the growth. *B. cereus* and other members of the *B. cereus* group except for *B. anthracis* readily decompose tyrosine.

Phage typing using bacteriophage gamma has been used for typing *B. anthracis*, *B. thuringiensis*, *B. sphaericus*, and *B. stearothermophilus*.

Serologic tests (precipitation and complement fixation) have been used to separate *B. anthracis* from other *Bacillus* species, but antisera to *B. anthracis* react to some extent with other bacilli, limiting their usefulness. Agglutination tests have been found to be of little value, as these bacteria have the tendency to agglutinate spontaneously (Sievers and Zetterberg, 1940).

Bacillus anthracis and other *Bacillus* species can be differentiated by lectin agglutination assays (Cole et al., 1984). The agglutination can be carried out on a microscope slide. *B. anthracis* and *B. mycoides* give a positive agglutination with lectin from soybean (*Glycine max*). Agglutination with lectin from the snail *Helix pomatia* is positive only for *B. mycoides*. Spores have lectin receptors, and heating at 100°C decreases the agglutination.

A comparison of gas-liquid chromatography, DNA-DNA hybridization, API systems, and classic biochemical tests for speciation of some *Bacillus* species found API systems to be superior (O'Donnell et al., 1980). This impression was confirmed by Logan and Berkeley (1984) in their study of 600 *Bacillus* strains. API systems supplemented with spore examination, motility testing, and gas from carbohydrate fermentation were more rapid, accurate, and reproducible than classic biochemical tests. API and phage sensitivity testing are superior to other methods for distinguishing partially virulent and avirulent strains of *B. anthracis* from closely related species (Logan et al., 1985a).

CHAPTER 1.2.19

Genera Related to the Genus *Bacillus*—*Sporolactobacillus*, *Sporosarcina*, *Planococcus*, *Filibacter* and *Caryophanon*

DIETER CLAUS, DAGMAR FRITZE AND MILOSLAV KOCUR

Phylogenetic studies using comparisons of the oligonucleotide sequences of 16S rRNA have shown that taxa might group together which, according to classical taxonomy, would not have been found to be closely related. For instance, Fox et al. (1977) have shown that *Sporolactobacillus* may well be included in the genus *Bacillus*, and reference is not an exact matchPechman et al. (1976) and Fox et al. (1977) demonstrated that *Sporosarcina ureae* is more closely related to *Bacillus pasteurii* than are several other species of *Bacillus*. Similar studies suggest that a number of species or even genera, which, hitherto, have been placed in either nonsporeforming or Gram-negative taxa, should be placed close to the genus *Bacillus* and in particular to those species forming spherically shaped spores (Clausen et al., 1985; Stackebrandt et al., 1987). The dendrogram constructed according to these results shows a close neighboring relationship of *Filibacter limicola* to *Bacillus globisporus*, *Planococcus citreus* to "*B. aminovorans*," and *Caryophanon latum* to *B. sphaericus*. The *Bacillus* species forming spherical spores showed a higher degree of relationship to these nonsporeforming organisms than to each other and, in particular, higher than to the *Bacillus* species forming oval to ellipsoidal spores.

Also, the genus *Marinococcus,* comprising three species, has been separated from the genus *Planococcus*. Ventosa et al. (1990) described *Salinicoccus,* a genus phenotypically similar to *Marinococcus* and *Planococcus*. Both genera will be discussed within this chapter although their phylogenetical relationships to the family Bacillaceae and in particular to *Planococcus* are not known.

The genus *Bacillus* seems to be phylogenetically incoherent, and the spherical-sporeforming *Bacillus* species may represent a separate evolutionary line within the genus (Bonde, 1981; Logan and Berkeley, 1981; Priest, 1981). This is supported by rRNA analyses (Stackebrandt et al., 1987).

The phenotypic differentiation of the genus *Bacillus* from other genera mainly utilizes the following features: aerobic, sporeforming, rod-shaped, and Gram-positive cell wall. Although these four characteristics seem to be unequivocal, it is not always easy to provide evidence for them.

The ability to form spores is sometimes difficult to demonstrate for a number of strains or even species of the various sporeforming bacteria. Some organisms originally described as nonsporeformers were reclassified after the detection of spores, e.g., "*Lineola longa*" as "*B. macroides*" (reference is not an exact matchBennet and Canale-Parola, 1965) and "*Lactobacillus cereale*" as *B. coagulans* (Gordon et al., 1973), and there may be more of these. Many strains of recognized species are known to easily lose their ability to form spores after only a few transfers on culture media. Special treatment is necessary to avoid this loss which is, in most cases, not a loss of genetic information but loss of the potency of expressing a property. A general procedure for the induction of spore formation in a culture, especially for regaining of the ability to form spores, cannot be given. Various methods have been described, each having its own advantages with certain strains or species. Methods vary from supplementation of media with trace elements, especially manganese ions or soil extract, to variations in the conditions of incubation and supply of nutrients. Most of these methods or references to them are given in reviews Claus and Berkeley (1986) and Kalakoutskii and Dobritsa (1984).

The requirement that the genus *Bacillus* be Gram-positive remains, although strains or species that are Gram-variable or Gram-negative are accepted. In many species, Gram-positive reactions are seen only in very young cultures. Wiegel (1981) proposed that a differentiation should be made between Gram reaction, a staining phenomenon and Gram type, which refers to the structure of the cell wall as seen in thin sections in the electron microscope. And, indeed, in many cases it has been shown that the cell wall of a Gram-negatively staining strain is actually Gram-positive in structure.

This chapter was taken unchanged from the second edition.

Minimal Descriptions of the Bacillaceae

In the following, a minimal description of the two sporeforming and the three nonsporeforming genera placed—on the basis of phylogenetic studies—into the family of the Bacillaceae is given in comparison with the genus *Bacillus* as currently defined.

Genus *Bacillus*

Staining mostly Gram-positive, rods, peritrichously flagellated, endospores ellipsoidal or spherical, swelling or not swelling the sporangium, aerobic to facultatively anaerobic, mostly catalase positive.

Genus *Sporolactobacillus*

Gram-positive, rods, sparse-peritrichously flagellated, ellipsoidal endospores, swelling the sporangium, aerobic to microaerobic, catalase negative.

Genus *Sporosarcina*

Gram-positive, spheres occurring in pairs, tetrads, or packages, often only one flagellum per cell, spherical endospores, aerobic, catalase positive.

Genus *Planococcus*

Gram-positive, spheres occurring in pairs or tetrads, one to three flagella per cell, asporogenous, aerobic, catalase positive.

Genus *Filibacter*

Stains Gram-negative but its Gram type is positive, multicellular filaments, motile through gliding, asporogenous, aerobic, catalase positive.

Genus *Caryophanon*

Gram-positive, multicellular large rods, peritrichously flagellated, asporogenous, aerobic, catalase positive.

The Genus *Sporolactobacillus*

During the course of studies on the distribution of microorganisms in assorted chicken feed, Kitahara and Suzuki (1963) isolated an unusual strain of a lactic acid bacterium possessing certain characters intermediate between those of the genera *Bacillus* and *Lactobacillus*. The rod-shaped strain was Gram-positive, motile, formed endospores, was microaerophilic and catalase negative, and showed a typical homofermentative metabolism, producing D(−)-lactic acid. The authors created the new subgenus *Sporolactoba-*

cillus within the family Lactobacillaceae in order to accommodate this unusual bacterium. Later, *Sporolactobacillus* was transferred as an independent genus comprising only one species, *Sporolactobacillus inulinus*, into the family Bacillaceae (Kitahara and Toyota, 1972).

Similar strains were isolated by Nakayama and Yanoshi (1967a) and by Amemiya and Nakayama (1980). They were grouped with *S. inulinus* or were considered to belong to a new species for which the names "*S. laevas*," "*S. laevas* var. *intermedius,*" and "*S. racemicus*" have been proposed (Yanagida et al., 1987a). The genus was reviewed by Norris (1981), Norris et al. (1981), and Kandler and Weiss (1986).

Habitats

The original isolate, classified as *Sporolactobacillus inulinus*, was from chicken feed (Kitahara and Suzuki, 1963). Nearly all other strains of sporolactobacilli have been isolated from the rhizosphere or from soil around root hairs of a variety of wild plants collected in Japan and Southeast Asia (Nakayama and Yanoshi, 1967b; Amemiya and Nakayama, 1980). From a total of about 700 samples collected in the United States (foods, feed, soil, environment), Doores and Westhoff (1983) were able to isolate only two strains of *Sporolactobacillus*, both from soil samples. These authors concluded, therefore, that the incidence of sporolactobacilli in the environment is extremely low. Nakayama and Yanoshi (1967a) have pointed out that the rhizosphere represents a habitat where nutrients necessary for the growth of lactic acid bacteria may be provided by excretion from root hairs. Since the rhizosphere has a tendency to undergo drying and heating by sunlight impinging on the soil surface, it would favor, besides other microorganisms, the growth of motile, sporeforming, lactic acid bacteria.

Isolation

Many *Sporolactobacillus* strains have been isolated by Nakayama and Yanoshi (1967b) and by Amemiya and Nakayama (1980) using the following method:

Isolation Method 1 (Nakayama and Yanoshi, 1967a)

> The enrichment medium for *Sporolactobacillus* has the following composition (*Sporolactobacillus* broth):

Glucose	10.0 g
Polypeptone	10.0 g
Yeast Extract	10.0 g
Sodium citrate	0.027 g
KH_2PO_4	0.5 g
K_2HPO_4	0.5 g
$MgSO_4 \cdot 7H_2O$	0.3 g
NaCl	0.01 g

MnSO$_4$ · 5H$_2$O	0.01 g
CuSO$_4$ · 5H$_2$O	0.001 g
CoCl$_2$ · 6H$_2$O	0.001 g
FeSO$_4$ · 7H$_2$O	0.001 g
Soil extract (see below)	100 ml
Distilled water	900 ml

Soil extract is prepared by autoclaving 100 g of garden soil mixed with 200 ml distilled water for 20 min at 130°C. The mixture is centrifuged to obtain a clear supernatant. The glucose broth is adjusted to pH 6.4 and is sterilized for 15 min at 115°C. Root material with root hairs and adherent soil from plants like *Trifolium repens*, *Allium japonicum*, *Ranunculus scelerata* and others is collected. Small pieces of the specimen are placed in a test tube containing a few ml of the sterile enrichment medium. In order to kill asporogenous organisms the tubes are heated at 80°C for 20 min and are incubated anaerobically at 30°C. In most tubes, clostridia will develop. On further incubation, however, the pH of cultures may drop below 4.0. Material from such cultures is streaked onto *Sporolactobacillus* agar composed of the broth described above supplemented with 10 g of calcium carbonate and solidified by 15 g of agar per liter of medium. After streaking; the agar surface is covered by a polyvinylidene chloride film, sterilized by autoclaving between filter papers, in order to depress the growth of aerobic bacteria. The plates are incubated aerobically at 30 to 37°C. Pin-point colonies with a transparent halo are picked, purified, and tested for the absence of catalase and the presence of endospores.

A selective technique for the enrichment and isolation of strains of the genus *Sporolactobacillus* has been developed by Doores and Westhoff (1983). Since the incidence of sporolactobacilli in the environment seems to be low, enrichment for these organisms is more likely to be successful than direct plating.

Isolation Method 2 (Doores and Westhoff, 1983)

Soil samples of about 5 g are collected aseptically in sterile 100-ml screw-cap bottles. To the soil sample, 50 ml of the following modified MRS broth is added:

α-Methylglucoside	10.0 g
Proteose peptone	10.0 g
Beef extract	5.0 g
Yeast extract	5.0 g
Tween 80	1.0 g
Ammonium citrate	2.0 g
Sodium acetate	5.0 g
Magnesium sulfate	0.1 g
Manganese sulfate	0.05 g
Disodium phosphate	2.0 g
Potassium sorbate	1.0 g
Bromocresol green	0.0224 g
Distilled water	1 liter

The medium is adjusted to pH 5.5 with 1 N acetic acid. After vigorous shaking for 2 min, the soil suspension is allowed to settle for about 5 min. Thereafter, the supernatant is transferred to a sterile 100-ml bottle, and the pH readjusted to 5.5 with 1 N or 0.1 N acetic acid or sodium hydroxide. The medium is incubated for 7 days at 30°C in a carbon dioxide incubator with a carbon dioxide level of 5% and a relative humidity of 98%. Thereafter, a 2-ml sample is transferred to a sterile test tube, which is then

heated for 5 min in a 80°C water bath to kill vegetative cells. Aliquots of 0.1 ml of the heat-treated sample are spread onto plates of modified MRS agar (modified MRS broth, pH 5.5 plus 15 g agar per liter of medium). The plates are incubated at 30°C. Colonies on the plates are screened for catalase production and benzidine reaction (both are negative for sporolactobacilli) as well as for the presence of spores and motility. The latter properties may be variable under the isolation conditions. Due to the specifity of the method, interference from environmental strains of *Bacillus* and *Lactobacillus* appears to be negligible.

Cultivation

Sporolactobacillus inulinus and other sporolactobacilli grow well on most media used for lactobacilli. In general, fermentable sugars are necessary for growth. Excellent growth has been observed on the GYP medium used by Kitahara and Suzuki (1963).

GYP Medium

Glucose	20.0 g
Yeast extract	5.0 g
Peptone	5.0 g
Agar	15.0 g
Distilled water	1 liter

Incubation should be at 30 to 37°C under an atmosphere containing 5% carbon dioxide (Doores and Westhoff, 1983). Under air, only feeble growth may occur.

A series of commercially available media also support good growth under the conditions described. These include ATP agar (BBL) and lactobacilli MRS agar (Difco). For growing a large number of strains of the sporolactobacilli, Yanagida et al. (1987a) successfully used the following medium:

Sporolactobacillus Growth Medium

Glucose	20.0 g
Yeast extract	10.0 g
Peptone	10.0 g
Sodium acetate	10.0 g
MgSO$_4$> · 7H$_2$O	0.2 g
MnSO$_4$ · 4H$_2$O	0.01 g
FeSO$_4$ · 7H$_2$O	0.01 g
NaCl	0.01 g
Agar	20.0 g
Distilled water	1 liter

Adjust to pH 6.8. Incubate plates at 30°C.

Growth factor requirements have only been studied with a single strain which required biotin, pantothenic acid, leucine, and valine (Kitahara and Suzuki, 1963).

Maintenance and Preservation

Strains of *Sporolactobacillus* may be stored in liquid media for several months at −20°C if the acidity of cultures is neutralized after growth has ceased. Cultures can be freeze-dried by common procedures, for example, in 20% skim milk sup-

plemented with 5% *myo*-inositol. Maximum viability of sporulated cultures is not known.

Cultural and Microscopic Appearance

On agar media, sporolactobacilli form pinpoint colonies which are circular with convex shape, grayish white, and glistening. Due to the formation of copious amounts of lactic acid, colonies on media containing calcium carbonate are surrounded by clear haloes. Growth is feeble on agar slants. In agar shake cultures, uniform growth can be observed except for a 5-mm zone near the surface.

Sporolactobacillus strains are Gram-positive or Gram-variable. They form slender rods which are sometimes slightly bent. Cells measure 0.7–0.8 × 3–5 μm and occur singly, in pairs, and rarely in short chains. They are motile by a small number of long, peritrichously inserted flagella. Endospores are formed in certain media (see below).

When cultured in tomato-meat (TM) medium (see below) devoid of ammonium sulfate and calcium carbonate, a large proportion of vegetative cells form tadpole-like structures.

Endospore Formation

In most media the formation of endospores is very rare. A sporulation rate of 10^{-4} to less than 10^{-6} has been observed. However, a medium in which sporulation takes place at a higher rate has been developed by Kitahara and Lai (1967). In this medium the sporulation frequency can be increased up to 10% by incubating cultures under 5% CO_2 at 37°C.

TM Medium for Sporulation of *S. inulinus* (Kitahara and Lai, 1967)

Yeast extract	1.0 g
Meat extract	5.0 g
α-Methylglucoside	5.0 g
Ammonium sulfate	10.0 g
Tomato serum	200 ml
Distilled water	800 ml

Adjust the pH of the medium to 5.5 and add 20 g calcium carbonate (precipitated material). Doores and Westhoff (1981) found that the above medium without tomato serum was superior. Nakayama and Yanoshi (1967b) found that starch stimulated the formation of endospores.

Spores are ellipsoidal and 0.9 to 1.4 × 1.0–2.1 μm in size. They appear in the terminal to subterminal position. The sporangia are definitely swollen. As with other bacterial spore-formers, endospores contain dipicolinic acid.

Spores of only one *Sporolactobacillus* strain have been studied for heat resistance. They tolerate a treatment of 10 min at 70–80°C but not at 90°C. Decimal reduction times have been reported by Doores and Westhoff (1981).

Ultrastructure

Thin sections of vegetative cells show the usual cell wall type of Gram-positive bacteria (Kitahara and Toyota, 1972). The ultrastructure of spores is similar to those of *Bacillus* spores (Kitahara and Lai, 1967).

Chemotaxonomy

The cell wall of *Sporolactobacillus inulinus* contains *meso*-diaminopimelic acid, a large amount of polysaccharides, but no teichoic acid (Weiss et al., 1967; Okada et al., 1976). Uchida and Mogi (1973) examined the fatty acid composition of *Sporolactobacillus* strains and found odd-numbered, saturated anteiso- and iso-branched fatty acids. No unsaturated, even-numbered or cyclopropane fatty acids, which predominate in members of the genus *Lactobacillus*, have been detected.

Collins and Jones (1979) studied the isoprenoid quinone composition of strains of *S. inulinus*, "*S. laevas*," and "*S. racemicus*," as well as strains of some *Bacillus* species. In all strains, menaquinones with seven isoprene units (MK-7) predominate. In *Lactobacillus* strains, neither menaquinones nor ubiquinones were detected.

Genetic and Phylogenetic Relationships

Published values on the GC content of the DNA of *Sporolactobacillus inulinus* vary greatly. Using paper chromatography, Suzuki and Kitahara (1964) reported that the GC content of the type strain was 39.3 mol%. For the same strain, Kandler and Weiss (1986) found 38 mol% (T_m) and Miller et al. (1970) 47.3 mol%. This latter value was confirmed by Yanagida et al. (1987b) who found 46.8–47.0 mol% (T_m) for two strains of the species.

Miller et al. (1970) studied the DNA-DNA hybridization between strains of *S. inulinus*, *Lactobacillus plantarum*, and *Bacillus coagulans* and reported that there were no cross-reactions among these strains. Hybridization studies of Yanagida et al. (1987b), covering 33 *Sporolactobacillus* strains, have shown that the genus is genetically heterogenous, comprising five DNA homology groups (Table 1). Strain clusters found by a numerical taxonomic study of Yanagida et al. (1987a) did not correspond to the five DNA homology groups.

Results from cataloging the oligonucleotide pattern of ribosomal 16S RNA (Fox et al., 1977) have shown that *Sporolactobacillus* may well be included in the genus *Bacillus*. In later studies (Stackebrandt et al., 1987), it was found that *S. inulinus* was the only species possessing a phylo-

Table 1. Properties of the DNA homology groups of the *Sporolactobacillus* strains.

Homology group	GC content (mol%)	Intragroup homology	Species (number of strains)
1	46.8–50.2	88–100%	*S. inulinus* (2) "*S. laevas* var. *intermedius*" (1)
2	42.5–47.4	70–100%	"*S. laevas*" (12) "*S. laevas* var. *intermedius*" (3)
3	42.9–46.2	55–100%	"*S. racemicus*" (7) "*S. laevas* var. *intermedius*" (2)
4	42.5–45.8	79–100%	"*S. racemicus*" (2) "*S. laevas* var. *intermedius*" (2)
5	43.0	100%	"*S. laevas*" (2)

Adapted from Yanagida et al. (1987b).

genetic position differing from that of the other aerobic or facultatively anaerobic Gram-positive sporeformers examined up to now.

The close relationship of *Sporolactobacillus* and *Bacillus* can also be seen from chemotaxonomical studies (see above).

Physiological and Biochemical Properties

Although the genus is described as microaerophilic, all strains studied can be grown under air, even on agar plates. Strains tested showed improved growth, however, in the presence of 5% carbon dioxide. Some strains have been described as facultatively anaerobic (Nakayama and Yanoshi, 1967b).

Sporolactobacillus strains grow between 15–20 and 40°C with an optimum temperature at around 30°C. Although growth-limiting pH values are not known, cultures grow at a pH as low as 5.0. Since the pH of the medium decreases during growth in glucose broth to 3.8 to 3.2 (*S. inulinus*) or to pH 4.4 (other sporolactobacilli), growth may also be possible at a starting pH of 4.5.

Sporolactobacillus strains do not form catalase. Most strains need fermentable carbohydrates for growth. Acid without gas is produced by nearly all strains of the different DNA homology groups from glucose, fructose, mannose, maltose, sucrose, and trehalose. Acid formation from other carbohydrates is variable. In contrast to other strains studied, strains belonging to *S. inulinus* do not form acid from galactose (Yanagida et al., 1987a).

The type strain of *S. inulinus* has been shown to ferment hexoses exclusively to D(–)-lactic acid (homolactic acid fermentation) producing less than 1% of volatile acids or ethanol (Kitahara and Suzuki, 1963). According to Yanagida et al. (1987a), however, most strains of the genus Sporolactobacillus however, form both D(–) and DL-lactic acid. These discrepancies have to be clarified.

Identification

It is not yet possible to group *Sporolactobacillus* isolates according to their phenotypic properties with the type species of the genus, *S. inulinus*, or with any of the other sporolactobacilli described. Also, isolates cannot be grouped by phenotypic properties with the different DNA homology groups described by Yanagida et al. (1987b). Additional studies on phenotypic properties of the large number of available sporolactobacilli are now necessary. Because of the close relationship of *Sporolactobacillus* to the genus *Bacillus*, it is important to study the group by the same methods used for the characterization of *Bacillus* strains (Claus and Berkeley, 1986).

It has to be emphasized that a clear distinction between the genera *Sporolactobacillus* and *Bacillus* is also not possible. *Sporolactobacillus* strains, which all are characterized by the formation of lactic acid, can be separated from lactic acid-forming *Bacillus* species (*B. coagulans*, *B. smithii*, "*B. laevolacticus*," "*B. racemilacticus*") only by their temperature relationships and/or by their negative catalase reaction. Other phenotypic properties which may be used in the differentiation from these *Bacillus* species have not been studied.

While the lack of catalase in *Sporolactobacillus* has been considered as the main criterion for its separation from the genus *Bacillus*, it should be noted that certain *Bacillus* species also lack this enzyme. These include *B. azotoformans* (Pichinoty et al., 1983), *B. larvae*, *B. lentimorbus*, *B. popilliae*, certain strains of *B. stearothermophilus* (Gordon et al., 1973), and *B. pulvifaciens* (Nakamura, 1984).

Applications

Polysaccharide production of strains of the genus *Sporolactobacillus* has been studied by Amemiya and Nakayama (1980). Water-soluble fructans are produced from sucrose which show antitumor activity.

The Genus *Sporosarcina*

From urea-containing enrichment cultures, Beijerinck (1901) repeatedly isolated packet-forming coccoid bacteria. In contrast to all other sarcinae known at that time, the isolates were found to be motile by flagella and formed endospores. Beijerinck described these isolates as the new species "*Planosarcina ureae.*"

The species was later transferred by Löhnis (1911) to the genus *Sarcina*, which at that time comprised bacteria that were morphologically similar due to the formation of packets (sarcinae) of four or more cells. In physiological and biochemical properties, however, the various *Sarcina* species of Löhnis differed from each other substantially. Therefore, "*Sarcina ureae*" was later separated from the genus *Sarcina* and transferred to the genus *Sporosarcina* (Kocur and Martinec, 1963; MacDonald and MacDonald, 1962) as previously proposed by Orla-Jensen (1909) and by Kluyver and van Niel (1936).

Strains of two species of the genus *Sporosarcina* are available now in pure culture and have been extensively described: *S. ureae* (Beijerinck, 1901) Kluyver and van Niel, 1936[AL], and *S. halophila* Claus, Fahmy, Rolf and Tosunoglu, 1984[VP]. Beijerinck (1901) briefly mentioned another sporeforming sarcina which he named "*Urosarcina dimorpha*," which developed only on media containing horse urine gelatin, but it is not certain whether pure cultures were isolated. Attempts to reisolate "*U. dimorpha*" have been unsuccessfull (D. Claus, unpublished observation). The only other described taxon of the genus is "*Sarcina pulmonum*," a motile, sporeforming urea-degrading organism isolated from clinical material, but these strains were subsequently lost. According to Gibson (1935), these isolates were probably identical with *Sporosarcina ureae*.

S. ureae and *S. halophila* are considered to be nonpathogenic for humans, animals, and plants. The genus has been reviewed by Claus (1981), Norris (1981), and Claus and Fahmy (1986).

Habitats

Like other sporeforming bacteria, *Sporosarcina ureae* is widely distributed in soil. Fertile soils may contain up to 10^4 sarcinae/g (Gibson, 1935; Pregerson, 1973). The bacterium probably has also been isolated from liquid manure (Sames, 1898). A single isolate has also been reported from sea water (Wood, 1946). Pregerson (1973) has found *S. ureae* to be widely distributed in the United States and in various other parts of the world. According to her studies, the primary habitat of the organism appeared to be concentrated in certain urban soils closely associated with the activities of humans and, especially, dogs.

The prevalence of the bacterium in fertile soils and certain other urea-containing places, its resistance against the inhibitory effect of up to 5–10% urea, and its ability to produce urease suggest that *S. ureae* plays an active part in the decomposition of urea in natural habitats.

The sporeforming "*Sarcina pulmonum*" was isolated at the beginning of this century by several workers from sputum and from the respiratory tract in cases of phthisis. Although for some time it was considered to be responsible for severe infections of the lungs, its pathogenicity has been questioned (Lehmann and Neumann, 1927; Gibson, 1935). Recently, a bacterial isolate from a bronchial biopsy in a young child with cystic fibrosis has been identified as *Sporosarcina ureae*. It was considered, however, not to be directly related to the disease (Chomarat et al., 1990).

S. halophila has been isolated from salt marsh soils (Claus et al., 1983), saline soils, and ponds of solar salterns (Ventosa et al., 1983). Its moderately halophilic characteristics, together with its obligate requirements for sodium, magnesium, and chloride ions, as well as its optimum temperature for growth (about 30°C), suggest that salt marsh and saline soils are the natural habitat of this species.

Isolation

Selective methods for the enrichment of the two accepted *Sporosarcina* species in liquid media have not been reported. The selective enrichment method used by Beijerinck (1901) for the isolation of *S. ureae* does not seem to work well. Strains of both species, however, can be isolated by plating soil dilutions on appropriate agar media.

ISOLATION OF *SPOROSARCINA UREAE*   The presence of *S. ureae* in many soil samples has been demonstrated by a simple and effective method (Gibson, 1935). Since 10% urea, as used by Gibson, may inhibit the growth of *S. ureae* from many soils, urea should be used at a concentration of only 3–5%. At this concentration, the growth of a high percentage of the bacterial soil flora is strongly inhibited. This is specifically true for *Bacillus mycoides*, which will readily overgrow most soil dilution plates at urea concentrations below 3%.

Method 1 for the Isolation of *S. ureae* (Gibson, 1935; Modified by Claus, 1981)

> To 1 liter of nutrient agar, add 30, 50, or 100 g of urea. Sterilize the media at 121°C for 15 min and pour into petri dishes. Suspend about 5 g of a soil sample (fertile soil, air-dried) in 20 ml of sterile water and prepare soil dilutions (10^{-1} and 10^{-2}). Plate 0.1 ml of the soil suspension and of the two dilutions on the agar and incubate at about 25°C. The soil suspension may be heated, but there is little or

no advantage to doing so because the majority of the organisms that develop on the media are sporeforming bacteria.

After 3–5 days, examine only cream or pale yellow to bright orange colored colonies under low magnification and transmitted light. Colonies of *S. ureae* can be recognized as round and black at a magnification of about 10×, and by their coarsely granulated structure, especially at the edges of the colonies, at a magnification of about 50×. With some experience, colonies of *S. ureae* may be selected with rather high certainty. Similar types of colonies, however are often formed by strains of *Bacillus megaterium*. Therefore, it is advisable to compare the colony types on isolation plates with those of known strains of the two species.

Prepare slides from selected colonies for observing the typical morphology of cells and confirm the provisional identification of isolated strains of *S. ureae* testing the motility and the production of spores (see below, under maintenance). Pure cultures are obtained by restreaking suspensions prepared from single colonies onto nutrient agar containing 2% urea.

Pregerson has isolated about 50 strains of *S. ureae* from 198 different soil samples and has proposed the following method for isolating the organism. A good source for isolation is soil from the base of trees where dogs have urinated.

Method 2 for the Isolation of *S. ureae* (Pregerson, 1973)

Tryptic soy-yeast (TSY) agar containing (per liter of distilled water); 27.5 g Difco tryptic soy broth, 5.0 g Difco yeast extract, 5.0 g glucose, and 15.0 g Difco agar, is adjusted with 1 N NaOH to pH 8.5 before autoclaving. Add aseptically filter-sterilized urea to give a final concentration of 1% (w/v) and pour the medium into petri dishes. Suspend 1 g of a soil sample in 15 ml of distilled water and mix the slurry with a Vortex mixer. Spread 0.1 ml of a series of dilutions on plates using a sterile bent glass rod. Prepare triplicate plates at 10^{-1} and 10^{-2} and duplicate plates at 10^{-3} and 10^{-4} dilutions.

Incubate at 22°C and examine the plates on the third day and then daily with a dissecting microscope. Colonies of *S. ureae* show a uniform-surface granularity, smoothly opaque interiors, and an orange or cream color. Prepare slides from selected colonies for observing cell morphology and motility and the production of spores (see below under maintenance), and isolate pure cultures.

The isolation of *S. ureae* from a certain soil sample often is not reproducible due to the irregular background growth developing on dilutions plates. A more selective method suppressing such growth or a selective liquid enrichment method will allow the isolation of this species also from soils where it is only present in low numbers.

Isolation of *Sporosarcina halophila* (Claus et al., 1983)

Two different agar media have been used for isolation. Bacto Marine Agar 2216 (Difco) is composed of:

Bacto peptone	5.0 g
Bacto yeast extract	1.0 g
Ferric citrate	0.1 g
Sodium chloride	19.45 g
Magnesium chloride	8.8 g
Sodium sulfate	3.24 g
Calcium chloride	1.8 g
Potassium chloride	0.55 g
Sodium bicarbonate	0.16 g
Potassium bromide	0.08 g
Strontium chloride	0.034 g
Boric acid	0.022 g
Sodium silicate	0.004 g
Sodium fluoride	0.0024 g
Ammonium nitrate	0.0016 g
Disodium phosphate	0.008 g
Agar	15.0 g
Distilled water	1 liter

Adjust the pH to about 7.5. The medium is sterilized at 121°C for 15 min and poured into petri dishes.

Alternatively, the following medium may be used:

Peptone	5.0 g
Meat extract	3.0 g
Sodium chloride	30.0 g
Magnesium chloride	5.0 g
Agar	15.0 g
Distilled water	1 liter

Adjust the pH to about 7.5

Suspend about 5 g of a sample of salt marsh soil in 20 ml of sterile tap water. Heat the suspension at 70°C for 10 min. Alternatively, the soil suspension may be treated with ethanol, final concentration 50% (v/v), for 1 h (to kill vegetative bacterial cells). Prepare soil dilutions in sterile water (10^{-1} to 10^{-4}). Plate 0.1 ml of the dilutions on agar medium.

After 3 days of incubation at 30°C, mainly pigmented (yellow, orange, or pink) colonies of various sizes of *Bacillus* species will have developed. Inspect the more crowded plates at a magnification of about 50× for round pin-point colonies which show, in transmitted light, a coarsely granulated structure at least at the edges of the colonies. The same colonies appear black under a magnification of only 10×. Check material of such colonies by phase contrast microscopy for the presence of sarcinae, which usually are motile or may have formed endospores.

For purification, suspend cell material taken from appropriate colonies in a drop of nutrient broth and streak onto plates of one of the agar preparations mentioned above. Colonies of *S. halophila* form an orange pigment which normally is not seen with the pin-point colonies developing on the isolation plates.

Fahmy et al. (1985) have observed that spores of *S. halophila* formed in pure culture will germinate only at a very low frequency in nutrient broth supplemented with 3% sodium chloride and 0.5% magnesium chloride, although growth of vegetative cells in such media is excellent. In contrast, a high percentage of spores readily germinate in nutrient broth supplemented with double-concentrated sea water (see below). This observation may be helpful in developing new media and methods for the selective enrichment and isolation of additional strains of *S. halophila* and to enumerate the species in natural samples.

Cultivation

Sporosarcina ureae grows well in normal nutrient broth. A more suitable medium contains, in addition, 1% urea or 0.5% ammonium chloride. In the latter case, the pH of the medium should be adjusted to 8.0 or 8.5. Since the organism is strictly aerobic, shaking is recommended to obtain high cell densities. The optimum temperature for growth is about 25°C.

A defined medium for *S. ureae* has been described by Goldman and Wilson (1977), which yields 5–6 g dry weight of bacteria per liter of culture.

S. ureae Growth Medium

L-Asparagine · H$_2$O, or L-Glutamine	30.0 g
KCl	3.4 g
K$_2$HPO$_4$	0.25 g
(NH$_4$)$_2$SO$_4$	0.2 g
MgSO$_4$ · 7H$_2$O	0.05 g
FeSO$_4$ · 7H$_2$O	0.0025 g
MnCl$_2$ · 4H$_2$O	0.00025 g
D-Biotin	0.001 g
L-Cysteine	0.005 g
Distilled water	1 liter

Prior to sterilization, the medium is adjusted to pH 8.7 with 1 M NaOH and supplemented with NaCl to a final concentration of 0.05 M Na+. Sterilized solutions of biotin (0.4 mg/ml), L-cysteine (2 mg/ml), and (NH$_4$)$_2$SO$_4$ (80 mg/ml) were added to the separately sterilized medium.

Pregerson (1973) has pointed out that the growth factor requirements of strains of *S. ureae* may vary substantially. From 61 isolates studied, 13 grew on a mineral acetate medium without added growth factors, but 37 strains required biotin either singly or in combination with niacin and/or thiamine. Some of these strains also needed aspartate. Eleven strains showed more complex growth factor requirements. Most of the strains could utilize acetate, butyrate, or glutamate as a sole source of carbon and energy. Glutamate, however, generally could not be used by *S. ureae* as the sole nitrogen source.

According to the definition of Larsen (1962), *S. halophila* is a slightly halophilic bacterium. It is one of the few "marine" bacteria which shows an obligate growth requirement for sodium, magnesium, and chloride ions. Sodium cannot be replaced by potassium nor chloride by sulfate. The salt requirements of the strains apparently reflect the natural habitat of the species.

In the presence of 30 to 50 g NaCl (maximum 150 g) and 5 g MgCl$_2$ per liter, all strains of the species studied show profuse growth on a variety of complex media. The pH optimum for growth is between pH 7.0 and 9.0 with an optimum at about pH 7.8. Strains grow from 15 to 35 or 40°C. The optimum temperature of growth is around 30°C. The species is strictly aerobic. It grows well on the following medium:

S. halophila Growth Medium

Peptone from meat	5.0 g
Meat extract	3.0 g
NaCl	30.0 g
MgCl$_2$	5.0 g
Agar	15.0 g
Distilled water	1 liter

Adjust the pH to 7.8.

Good growth is also observed on Bacto Marine Broth 2216 or Bacto Marine Agar 2216 (Difco). A chemically defined medium for *S. halophila* has not yet been developed.

Maintenance and Preservation

Vegetative cultures of *S. ureae* and of *S. halophila* may be kept for more than 8–12 weeks at about 4°C on nutrient agar slants if protected from drying. In tightly closed tubes, sporulated cultures (see below) may survive for several years if stored at 4°C. Sporulated cultures (see below) remain viable for more than one year.

For long-term maintenance, vegetative cells and spores of *S. ureae* and *S. halophila* can be preserved for years without significant loss in viability by lyophilization in skim milk (20% w/v) in the presence of 5% *myo*-inositol. Vegetative and sporulated cells can also be preserved for long periods in liquid nitrogen in the presence of a suitable cryoprotective agent like 5% (v/v) dimethylsulfoxide or 10% (v/v) glycerol (D. Claus, unpublished observations).

Cultural and Microscopic Appearance

Colonies of *Sporosarcina ureae* on agar are gray, opaque, circular, and slightly convex with an entire margin. On some media, a yellowish, brownish, or orange nondiffusible pigment may be produced. *S. halophila* forms round, smooth, and opaque colonies. Irrespective of the medium used, an orange nondiffusible pigment is formed.

The typical cell shape of both species is spherical. Often cells are modified by interfacial flattening in the cell aggregates. Especially in *S. halophila*, oval- to egg- or pear-shaped cells are also formed. The diameter of spherical cells is 1.0–2.5 μm. Oval cells of *S. halophila* measure 1–2 × 2–3 μm. Division walls usually are at right angles to one another.

In cultures of both species, various cell aggregate patterns can be found. Single cells, pairs, threes, tetrads, or packets are common or may predominate, depending on the medium used. In older cultures, aberrant forms often can be found: abnormally large cells appearing singly or within packets, short chains, or irregular packets. Apparently, this is due to an asynchronous cell division.

Cells and aggregates usually show a tumbling motility. With *S. ureae*, this is best observed using material from nutrient broth containing 1% urea (Kocur and Martinec, 1963). Most often, a single flagellum is formed per cell. It is difficult, however, to determine the precise number and location of flagella in cell packets (Sersen et al., 1983). *S. halophila* forms motile cells in young cultures grown on the agar media decribed above.

Endospore Formation

Both species form endospores under certain growth conditions. They are highly refractile, round, 0.5–1.5 μm in diameter, and located centrally or laterally. Like those of most *Bacillus* species, they resist heating for 10 min at up to 80°C or even more.

Spores of *S. ureae* can be obtained on one of the following sporulation media if the incubation temperature is lower than 22°C.

Sporulation Medium 1 for *S. ureae* (Gibson, 1935)

Peptone	5.0 g
Meat extract	5.0 g
Ammonium chloride	5.0 g
Agar	15.0 g
Distilled water	1 liter

Adjust the pH to 6.8–7.0.

Sporulation Medium 2 for *S. ureae* (Claus, 1981)

Peptone	5.0 g
Meat extract	3.0 g
Manganese chloride	50.0 mg
Agar	20.0 g
Distilled water	1 liter

The pH is not adjusted. After sterilization (20 min at 121°C) 20 ml of a filter-sterilized solution containing 10% (w/v) urea is added per liter of medium.

Sporulation Medium 3 for *S. ureae* (MacDonald and MacDonald, 1962)

Yeast extract	2.0 g
Peptone	3.0 g
Glucose	4.0 g
Malt extract	3.0 g
K_2HPO_4	1.0 g
$(NH_4)_2SO_4$	4.0 g
$MgSO_4$	0.8 g
$CaCl_2$	0.1 g
$MnSO_4 \cdot H_2O$	0.1 g
$FeSO_4 \cdot 7H_2O$	0.001 g
$ZnSO_4$	0.01 g
$CuSO_4 \cdot 5H_2O$	0.01 g
Agar	30.0 g
Water	1 liter

Adjust the pH before sterilization to 8.8–9.0.

At 22°C, all strains isolated by Pregerson (1973) showed production of spores on the latter medium. However, considerable variation in the onset and extent of sporulation was observed.

Some strains produced only a few spores after 4 weeks of growth, while others produced an abundance of spores within 4 days. Some strains produced spores more readily when the peptone of the medium was replaced by casamino acids (Difco). Crowded conditions on plates apparently stimulated spore formation.

Spore formation of *S. halophila* initially was good on Difco Marine Agar 2216 (composition see above). This property was totally lost by all strains after purification and few transfers on this medium. However, with most strains, sporulation could be retained by growing cultures on the seawater agar of Lyman and Fleming (1940) and by incubating the cultures at 22°C (Fahmy et al., 1985).

Seawater Agar

Bacto peptone (Difco)	5.0 g
Yeast extract	1.0 g
Ferrous phosphate · 4H₂O	0.1 g
Manganese chloride	0.01 g
Agar	15.0 g
Synthetic seawater (see below)	1 liter

The pH of the medium is adjusted to 7.1 before sterilization.

Synthetic Seawater

Distilled water	1 liter
Sodium chloride	24.32 g
Magnesium chloride · 6H₂O	10.99 g
Sodium sulfate	4.06 g
Calcium chloride · 2H₂O	1.51 g
Potassium chloride	0.69 g
Sodium bicarbonate	0.20 g
Potassium bromide	0.10 g
Strontium chloride · 6H₂O	0.042 g
Boric acid	0.027 g
Sodium silicate · 9H₂O	0.005 g
Sodium fluoride	0.003 g
Ammonium nitrate	0.002 g
Ferrous phosphate · 4H₂O	0.001 g

Like endospores of the genus *Bacillus*, the endospores of the two *Sporosarcina* species contain the spore-specific compound dipicolinic acid, which has never been found in vegetative bacterial cells (Fahmy et al., 1985; MacDonald and MacDonald, 1962; Thompson and Leadbetter, 1963).

Ultrastructure

Studies on the fine structure of vegetative cells, including regular surface layers, have been published for *S. ureae* (Beveridge, 1979; Beveridge, 1980; Engelhardt et al., 1986; Mazanec et al., 1965; Robinson and Spotts, 1983; Silva et al., 1973; Stewart and Beveridge, 1980). The ultrastructure of spores of both *Sporosarcina* species is similar to that of *Bacillus* spores (Silva et al., 1973; Robinson and Spotts, 1983; Fahmy et al., 1985).

Chemotaxonomy

Whereas the cortex of *Sporosarcina* spores, like all *Bacillus* species studied, contains *meso*-diaminopimelic acid, this compound has not been detected in the walls of vegetative cells of both *Sporosarcina* species (Claus et al., 1983; Ranftl, 1972; Schleifer and Kandler, 1972). The peptidoglycan types found in vegetative cells, however, differ with the two species. For *S. ureae*, the lys-gly-D-glu type has been described (Linnett et al., 1974; Schleifer and Kandler, 1972), whereas in *S. halophila*, the orn-D-asp type is found (Kandler et al., 1983). Also in cell wall preparations of *S. halophila*, high amounts of a gamma-D-glutamyl polymer have been detected, but this compound is not present in *S. ureae* (Kandler et al., 1983).

The menaquinone system of both species is MK-7. This corresponds to the one found in most species of the genus *Bacillus* (Claus et al., 1983; Collins and Jones, 1981; Yamada et al., 1976).

Except for the observation that cell membranes of *S. ureae* contain phosphatidylethanolamine (Komura et al., 1975), other data of chemotaxonomic relevance have not been published.

Genetic and Phylogenetic Relationship

The GC content for 11 strains of *S. ureae* has been found to be in the range of 40.0–41.5 mol% (T_m) (Bohácek et al., 1968b) and for three other strains, from 40.6–40.8 mol% (T_m) (Claus et al., 1983). DNA-DNA hybridization studies have been performed only with two strains of the species. The binding between these is 93% (Fahmy, unpublished observations).

The GC content of 22 strains of *S. halophila* was determined to be in about the same range (40.1–40.9 mol%; T_m). According to DNA-DNA hybridization studies, the species is homogenous; the homology of the DNA of the 22 strains studied is from 72–100%. The DNA homology between the type strains of the two species, however, is only 36% (Claus et al., 1983).

A close relationship of the sporeforming genera *Sporosarcina* and *Bacillus* was already suggested by Beijerinck (1901), who observed the occurrence of soil bacteria morphologically intermediate between *S. ureae* and *Bacillus megaterium*.

The genetic relationship of the two genera was first studied by Herndon and Bott (1969) using DNA-RNA hybridization methods. By comparative 16S rRNA cataloging, reference is not an exact matchPechman et al. (1976) and Fox et al. (1977) have shown that *S. ureae* is more closely related to *Bacillus pasteurii* than are several other species of *Bacillus*. These authors concluded that *S. ureae* should best be classified as a member of the genus *Bacillus*. In the eighth edition of *Bergey's Manual of Determinative Bacte-riology*, however, the genus *Sporosarcina* was given generic rank in the family Bacillaceae (Gibson, 1974).

The close phylogenetic relationship of *S. ureae* to members of the genus *Bacillus* has been confirmed by Stackebrandt et al. (1987). *S. ureae* forms spherical endospores and is found to cluster with other *Bacillus* species forming spherical spores (e.g., *B. pasteurii*, *B. sphaericus*). This group, which also includes some non-sporeforming bacteria, is separated from those *Bacillus* species forming ellipsoidal endospores (e.g., *B. subtilis*, *B. cereus*, *B. megaterium*, *B. pumilus*). These and other studies on the bacterial phylogeny suffer from the fact that very often the type strain of the species were not used.

The phylogenetic relationship of *S. halophila* to *S. ureae* or to members of the genus *Bacillus* has not been reported.

The nucleotide sequence of the 5S rRNA of *S. ureae* has been published by Park et al. (1988).

Physiological and Biochemical Properties

The general properties of *S. ureae* have been described by Kocur and Martinec (1963) and by MacDonald and MacDonald (1962). The results have been confirmed using the methods described by Gordon et al. (1973) for the characterization of *Bacillus* species (D. Claus, unpublished observations). Properties of *S. halophila* have been studied by Claus et al. (1983), using, as far as possible, the same methods. All media, however, were supplemented with 3% NaCl and 0.5% $MgCl_2$. The properties of the two species are listed in Tables 2 and 3.

Identification

The two *Sporosarcina* species can easily be differentiated by the series of phenotypic properties listed in Table 2. They can clearly be

separated from morphologically similar cocci by the characters listed in Table 4.

Other Studies

Beijerinck (1901) and Gibson (1935) indicated that urea can be hydrolyzed by *Sporosarcina ureae* at concentrations of up to 5–10%. Urease was characterized as an exoenzyme by Pel'ttser (1969) and quantified by Kaltwasser et al. (1972). The presence of enzymes required for a functioning urea (ornithine) cycle in *S. ureae* has been demonstrated by Gruninger and Goldman (1988). A strain of *S. ureae* was included in studies on the esterase pattern of psychrotrophic *Bacillus* species (Higashi and Johnson, 1986).

A bacteriophage of *S. ureae* was first isolated by Kluckhohn and Spotts (1986). Jensen and Stenmark (1970) characterized the control mechanism of 3-deoxy-D-arabinoheptulosonate-7-phosphate synthetase and have shown that the control pattern resembled that of species in the genus *Bacillus*.

Applications

Intracellular L-phenylalanine dehydrogenase of *Sporosarcina ureae* can be used for the efficient enzymatic transformation of phenylpyruvate to L-phenylalanine (Asano and Nakazawa, 1985; Campagna and Bückmann, 1987). The enzyme was highly purified and crystallized by Asano and Nakazawa (1985). It can also be used for the high yield synthesis of other L-amino acids from their keto analogs by combination with formate dehydrogenase (Asano and Nakazawa, 1987).

The Genus *Planococcus*

Motile cocci were first isolated by Ali-Cohen (1889) and were named "*Micrococcus agilis*." Migula (1894) established, for motile cocci, the new genus "*Planococcus*," which he placed into the family Coccaceae (Migula, 1900). However, most bacterial taxonomists continued to include motile cocci in the genus *Micrococcus*, as they are very similar in cultural and biochemical characteristics to true micrococci. Bohácek et al. (1967, 1968a) determined the GC content of some micrococci and concluded that non-motile cocci are not taxonomically related to motile strains. Kocur et al. (1970) studied the taxonomy of motile cocci and revived and amended the genus *Planococcus* Migula 1894 with the type species, *P. citreus*.

Only two species are now recognized in the genus, *P. citreus* Migula 1894, 236[AL] and *P. kocurii* Hao and Komagata 1986[VP]. As a result of chemotaxonomical studies, the species *P. halophilus* reference is not an exact matchNovitski and Kushner 1976, 53[AL] was transferred to a new genus called *Marinococcus* (Hao et al., 1984).

Habitats

Planococci have been isolated from marine environments, sea water (ZoBell and Upham, 1944), marine clams (Leifson, 1964), fish-brining tanks (Georgala, 1957), and boiled and frozen shrimps and prawns (Alvarez, 1982; Hao and Komagata, 1985). They play a role in food hygiene because they may cause putrefaction of shrimps during storage (Alvarez, 1982).

Isolation

No selective medium for the isolation of planococci has been devised. For their isolation, seawater agar or nutrient agar supplemented with 10% NaCl may be used.

Seawater Agar

Beef extract	10 g

Cultivation

Planococci can be cultivated on seawater agar, on peptone-yeast agar, or on nutrient agar supplemented with up to 10% sodium chloride.

Maintenance and Preservation

Cultures of planococci may be maintained on slants of seawater agar at 4°C for about 6 months. Strains can be preserved in a freeze-dried state or in liquid nitrogen for long periods.

Cultural and Microscopic Appearance

Colonies of planococci are circular, slightly convex, smooth, and yellow-orange in color due to water-insoluble carotenoid pigments. Pigmentation as well as the type of carotenoids produced may be influenced by the concentration of sodium chloride in the medium and by the age of the culture (Thirkell and Summerfield, 1980). A hydrostatic pressure of 40 MPa has no influence on the pigment production of *P. citreus* (Courington and Goodwin, 1955).

The genus includes Gram-positive, nonsporforming, spherical cells of 1.0 to 1.2 μm in diameter, occurring singly, or in pairs, tetrads, or clumps. Motile cells usually have one to three flagella. Endospores are not formed.

Ultrastructure

The fine structure of the cells of *Planococcus citreus* is similar to that of other Gram-positive, catalase-positive cocci. The cell wall is double layered. Its thickness varies with the cell age from 25–35 nm (Kocur, 1986).

The concentration of salt in the medium affects the amount of membrane in the cell of *P. citreus*. Salt concentrations above and below the normal 3% of sea water apparently reduce the amount of membrane material present (Thirkell and Summerfield, 1977a).

Chemotaxonomy

The cell wall peptidoglycan of both *Planococcus* species is of the L-lys-D-glu type (Schleifer and Kandler, 1970; Hao and Komagata, 1985). No teichoic acid was found in the cell wall of planococci (Endresen and Oeding, 1973). *Marinococcus* species, in contrast, have a cell wall of the *meso*-diaminopimelic acid type.

In common with other Gram-positive bacteria, *P. citreus* contains *anteiso* $C_{15:0}$ as the major component of free fatty acids. Phospholipids detected in planococci are similar to that of *Sporosarcina* and include phosphatidylethanola-

mine, cardiolipin, and phosphatidylglycerol (Yamada et al., 1976; Thirkell and Summerfield, 1977b; Hao and Komagata, 1985).

Planococci contain normal menaquinones, with MK-8 and MK-7 in about equal amounts. A small amount of MK-6 is also present (Hao and Komagata, 1985).

Genetic and Phylogenetic Relations

The analysis of the GC content revealed two groups among *Planococcus* species. Strains of *P. citreus* show 47 to 52 mol% (T_m), while the DNA base composition of *P. kocurii* is in the range of 39–42 mol% (T_m) (Bohácek et al., 1967, 1968; Hao and Komagata, 1985). Strains of *Marinococcus*, earlier grouped with *Planococcus*, have a GC content in the range of 43.9 to 46.6 mol% (T_m) (Hao et al., 1984). DNA-DNA hybridization studies have not been performed within the genus.

A comparative analysis of 16S rRNA sequences has shown that planococci bear no specific relationship to the genera *Micrococcus* and *Staphylococcus* (Stackebrandt and Woese, 1979). Planococci show a specific relationship to the genus *Bacillus*, particularly to *Bacillus pasteurii*, and to the genus *Sporosarcina* (Bohácek et al., 1968b, Pechman et al., 1976; Stackebrandt and Woese, 1979). The data on the GC content and the chemical composition of the cell wall support these observations (Bohácek et al., 1968b; Schleifer and Kandler, 1970). There is no antigenic relationship of planococci to staphylococci and micrococci (Oeding, 1971). In the light of the above facts, therefore, the genus *Planococcus* should be placed into the family Bacillaceae as a separate genus.

Physiological and Biochemical Properties

Strains of *Planococcus citreus* and *P. kocurii* can grow in the absence of sodium chloride but can also tolerate as much as 10% sodium chloride. They grow in the range of 5–30°C. Growth at 37°C is variable. Their biochemical activities are rather restricted (Table 4). They are catalase positive and hydrolyze DNA and gelatin (variably). Acid is formed from glycerol and glucose (variably), but not from other sugars or sugar alcohols.

Planococci are negative for the following reactions: oxidase, methyl red, Voges-Proskauer, production of indole, H_2S, nitrate reduction, phenylalanine deaminase, lysine decarboxylase, ornithine decarboxylase, arginine dihydrolase, urease, degradation of tyrosine, and hydrolysis of starch, esculin, and Tween 80. Assimilation of a

series of organic acids is variable or negative (Hao and Komagata, 1985).

Planococci are susceptible to lysozyme, chloramphenicol, erythromycin, novobiocin, oleandomycin, penicillin, and tetracycline (Jeffries, 1969; Kocur et al., 1970).

P. citreus was found to be one of the few marine bacteria that reproduced at a hydrostatic pressure of 20 to 40 MPa (Oppenheimer and ZoBell, 1952).

Identification

Planococci may be clearly separated from morphologically similar cocci by the characters listed in Table 4. They differ from the species of the genus *Marinococcus* by their ability to grow on media without NaCl added and by their inability to grow on peptone-yeast agar supplemented with 15% NaCl. *Sporosarcina halophila* differs from planococci in endospore formation, inability to grow on media containing 15% NaCl, esculin hydrolysis, and several chemotaxonomic characters. The two *Planococcus* species can be differentiated phenotypically only by their ability to grow on media containing 15% NaCl, which is positive only for *P. citreus*.

However, differentiation is also possible through their DNA base composition, zymogram, and protein pattern. They can also be separated serologically, as shown by Oeding (1971).

The Genus *Marinococcus*

The genus *Marinococcus* includes Grampositive, aerobic, and moderately halophilic cocci with *meso*-A_2pm acid in the cell wall. The genus was established by Hao et al. (1984) who transferred *Planococcus halophilus* reference is not an exact match Novitzki and Kushner (1976) into this genus and described the new species *Marinococcus albus*. Another new species, *M. hispanicus* has been isolated from a solar saltern (Marquez et al., 1990).

Habitat

Marinococci have only been isolated from marine environments, particularly from solar salterns (Ventosa et al., 1983; Marquez et al., 1990).

Isolation

No selective medium for the isolation of marinococci has been described. For their isolation, the salt complex medium of Ventosa et al. (1982) may be used.

Salt Complex Medium (Ventosa et al., 1982)

NaCl	8.1 g
MgCl$_2$	0.7 g
MgSO$_4$	0.96 g
CaCl$_2$	0.036 g
KCl	0.2 g
NaHCO$_3$	0.006 g
NaBr	0.026 g
Yeast extract	1.0 g
Proteose peptone No. 3	0.5 g
Glucose	0.1 g
Bacto-Agar (Difco)	20.0 g
Water	1 liter

Adjust to pH 7.5.

Cultivation

Marinococci can be cultivated on salt complex medium (Ventosa et al., 1982).

Maintenance and Preservation

Cultures of *Marinococcus* may be kept for 6 months at about 4°C on salt complex medium (Ventosa et al., 1982) if protected from drying. Cultures can be preserved in the freeze-dried state or in liquid nitrogen for long periods.

Genetic and Phylogenetic Relationships

The GC content of marinococci is in the range of 44.9–49.3 mol% (Hao et al. 1984; Marquez et al., 1990). DNA-DNA hybridization studies have not been performed within the genus.

Physiological and Biochemical Properties

Strains of *Marinococcus* species grow well in media with 20% sodium chloride, but not on media without salt. They grow in the range of 15–37°C. Like the planococci, the biochemical activity of the marinococci is restricted. They are catalase positive but oxidase production varies with species. *M. halophilus* and *M. hispanicus* may produce acid from glycerol and hydrolyze gelatin and esculin.

Marinococci are negative for the following reactions: acid from lactose, arabinose, galactose, and fructose; production of acetoin and indole; hydrolysis of starch and Tween 80; lysine and ornithine decarboxylases, arginine dihydrolase, phenylalanine deaminase, phosphatase, and growth on nutrient agar without sodium chloride.

Identification

Marinococci may be clearly separated from morphologically similar genera by the characteristics listed in Table 4. The three *Marinococcus* species can be differentiated by several phenotypic properties which are also listed in Table 4.

The Genus *Salinicoccus*

The genus *Salinicoccus* has been described quite recently (Ventosa et al., 1990). Its characteristics are based on only one strain which was isolated from a solar saltern near Alicante (Spain). The properties of this moderately halophilic nonsporeforming coccus are significantly different from all other hitherto described cocci. This justifies its recognition as a new species in a new genus.

The characteristics which distinguish *Salinicoccus roseus* from the phenotypically similar Gram-positive cocci are given in Table 4. There are no data on the ultrastructure, or the genetic and phylogenetic relationships of *S. roseus*.

The Genus *Filibacter*

A study of filamentous bacteria in sediments of lakes (Maiden, 1983) resulted in the isolation of an organism that resembled members of the genus *Vitreoscilla* in that it was a multi-cellular, filamentous, gliding bacterium that was not pigmented. Major differences in cytochrome and DNA base composition, isoprenoid quinone content, and sensitivity to actinomycin D seemed to indicate a more close relationship to the Flexibacteriaceae. As the organism did not resemble any previously described taxon of Flexibacteriaceae and on the basis of differences from both, it was proposed that the organism be placed in a new genus, *Filibacter*, with the type species *Filibacter limicola* Maiden and Jones, 1985, 375[VP] (Maiden and Jones, 1984).

Habitat and Isolation

Filibacter limicola has only been isolated once, from sediments of an eutrophic freshwater lake in the English Lake District, Blelham Tarn (Maiden, 1983). For isolation, sediment cores are sampled and treated according to Maiden and Jones (1984) as follows:

Isolation Procedure for *F. limicola*

> The top 1 to 2-cm layer of a sediment core is taken and diluted in filtered lake water. 10 µl of the sample are used for inoculation of plates containing the following medium:

MYP Medium (Maiden and Jones, 1984)

Peptone (Oxoid, L37)	0.1 g
Yeast extract (Difco)	0.01 g
K_2HPO_4	0.028 g
$MgCl_2 \cdot 6H_2O$	0.127 g
KNO_3	0.004 g
$(NH_4)SO_4$	0.06 g
$MnSO_4 \cdot 4H_2O$	0.008 g
Ferric citrate	0.006 g
Agar	10.0 g
Distilled water	1 liter

The pH of the medium is adjusted with potassium hydrogen carbonate to give a final pH of 7.0. The plates are incubated at 20°C for two weeks. They are periodically examined for growth of filaments through a dissecting microscope at a magnification of about 30×. *Filibacter* filaments may occur singly, in small groups, or in circular formations at some distance from the inoculation point. Purification may be done by excising small agar blocks with a single or a few attached filaments and transferring them to fresh medium. This procedure is repeated until pure cultures are obtained.

Cultivation

Pure cultures may be grown at about 20°C on nutrient agar (Oxoid CM 3), tryptone soya agar (TSA, Oxoid CM 131), or on the defined medium used for the isolation. Good growth is also obtained on media containing certain amino acids and vitamins as the sole source of carbon and nitrogen source (Maiden and Jones, 1984).

Cultures, incubated at 20°C, can be maintained on slants of TSA at 10°C for some weeks.

Cultural and Microscopic Appearance

Growth on solid media is characterized by spreading whorls of growth and spiral colonies which are not pigmented. The organisms exhibit gliding motility and grow in filaments of 8–150 µm where the individual cells are 3–30 µm long and about 1 µm wide. The cells are long rods that are either straight, or curved with rounded ends. Junctions between individual cells are marked by constrictions.

Capsules and sheaths are not formed but slime is excreted. Endospores and flagella as well as branching are not observed. Granules staining with sudan black were demonstrated but the test of Oste and Holt (1982) for poly-β-hydroxybutyrate is negative. Volutin granules are not observed. The cells stain Gram-negatively, although the cell wall is about 40 µm thick, lacks an outer membrane, and therefore shows the characteristics typical of a Gram-positive organism. Electron micrographs of thin sections showed a five-layered cell wall (Clausen et al., 1985).

Chemotaxonomy

Membrane fatty acids of *F. limicola* are dominated by anteiso-$C_{15:0}$ and anteiso-$C_{17:0}$ components (Nichols et al., 1986). The cell wall of *Filibacter limicola* contains no diaminopimelic acid and MK-7 is the major quinone isoprenolog. Cytochromes of the *c* type were determined to predominate, with lesser amounts of *b*-type cytochromes (Maiden and Jones, 1984).

Genetic and Phylogenetic Relationship

The GC content of the DNA of the type strain is 44 mol% (T_m) (Maiden and Jones, 1984). Comparative 16S rRNA cataloging studies show that *Filibacter* clusters with the Gram-positive species *Bacillus globisporus*, with which it forms a branch within a grouping that comprises also *Caryophanon latum*, *Sporosarcina ureae*, *Planococcus citreus*, and other spherical sporeforming *Bacillus* species. Several phenotypic properties support the allocation of this organism to the family Bacillaceae.

Physiological and Biochemical Properties

The organism is strictly aerobic in the temperature range around 20°C, with 4°C as a minimum and no growth at 30°C. Catalase and oxidase are present. Casein or starch are not hydrolyzed whereas gelatin is. Sulfur globules are not deposited intracellularly in the presence of sulfide. Urease is present. Carbohydrates are not degraded. The only compounds which are weakly used as carbon sources in the presence of amino acids are acetate, lactate, butyrate, and glycerol.

A similarly narrow range of carbon sources can be found with spherical sporeforming *Bacillus* strains such as *B. pasteurii* or *B. sphaericus*, with strains of the genus *Caryophanon*, or with *Planococcus* strains.

Identification

Filibacter limicola is morphologically similar to *Vitreoscilla stercoraria* but not to the two other *Vitreoscilla* species described. Differences to *V. stercoraria* are listed in Table 5. It should be emphasized, however, that only one strain of each of the two species has been compared.

The Genus *Caryophanon*

The genus name *Caryophanon* (karyon [Greek] = nucleus; phaneros [Greek] = bright, conspicu-

ous, that which has a conspicuous nucleus) is a misnomer, arising from the original false conclusion that the cross-walls, nuclear material, and cytoplasm seen in stained trichomes was a nucleus. The true nature of the trichomes was shown by improved cytological techniques (Pringsheim and Robinow, 1947).

Historically, *C. latum* played a significant role in the development of bacterial cytology in the 1940s and 1950s: Because of the large size of its trichomes and its numerous stainable "nuclei," *Caryophanon* provided an ideal model in the "great mitosis" debate (Tuffery, 1955).

Today, two species are recognized, *Caryophanon latum* Peshkoff 1939, 244[AL] and *Caryophanon tenue* (Peshkoff) Trentini 1988, 220[VP] (effective publication: Trentini 1986, 1259). Affiliation of the genus to already known, specific taxa was always difficult. Trichome-forming bacteria are a diverse group of organisms that have as a common property an outer cell wall that holds together the individual cells of the trichome.

In the seventh edition of *Bergey's Manual of Determinative Bacteriology* (1957) the order Caryophanales was described to include trichome-forming organisms comprising three families: Caryophanaceae, Oscillospiraceae (sporeforming organisms, not in pure culture) and Arthromitaceae. Later, in the eighth edition of *Bergey's Manual* (1974), *Caryophanon* was listed under Part 16: Gram-Positive, Asporogenous Rod-shaped Bacteria: Genus of Uncertain Affiliation. In *Bergey's Manual of Systematic Bacteriology, Caryophanon* was placed into Section 14: Regular, Nonsporing, Gram-positive Rods. However, recent rRNA sequencing studies have revealed a close relationship of *Caryophanon* to the aerobic sporeforming bacteria (Stackebrandt et al., 1987).

Habitat

Caryophanon latum was first isolated in 1937 and *C. tenue* in 1938 from fresh cow manure (Peshkov, 1939). In most of the successive studies, cattle manure was used as the primary source of these organisms (Gershenfeld and Lam, 1953; Kele, 1970; Moran and Witter, 1976; Peshkov and Marek, 1973; Pringsheim and Robinow, 1947; Provost and Doetsch, 1962; Smith and Trentini, 1972; Trentini and Machen, 1973; reference is not an exact match Tuffery, 1955; Weeks and Kelley, 1958). Reports that *C. latum* has been found in or on other sources such as sewage (Tuffery, 1953), the oral cavity of dogs (Saphir and Carter, 1976), or decaying *Pleurotus* on the stump of a tree (R. E. Buchanan, unpublished observations) could not be verified. Other findings that *Caryophanon* occurs associated with manure of

other animals (Kele, 1970; Trentini and Machen, 1973; reference is not an exact match Dean, 1973) may be doubted because of possible contamination of these sources with cattle manure.

Most samples taken from rumen fluid, cattle saliva, teeth scrapings, anal swabs, or rectal and intestinal samples from slaughtered cattle were negative for *Caryophanon*. Also, *Caryophanon* was not found in aseptically sampled cattle manure. It may, therefore, be concluded that these bacteria are not residents of the bovine digestive tract (Pringsheim and Robinow, 1947; Trentini and Machen, 1973; Kele, 1970; Dean, 1963).

Isolations of *Caryophanon* are easiest from 1- to 2-day-old droppings, whereas old field-dried cattle manure was usually negative for these organisms. Although the natural habitat of *Caryophanon* is not definitely known, it is assumed that these bacteria are secondary contaminants of cattle manure, dispersed to new droppings by air, by insects, or by the cattle itself.

Enrichment and Isolation

Caryophanon strains can be isolated only after an enrichment step. Good enrichment results are regularly obtained with fresh droppings from the barn gutters found with stanchioned cattle or with pasture manure after 1 to 2 days of field-aging as long as little or no rain has fallen during that time and the temperature has not fallen below 0°C.

Enrichment Procedure (Pringsheim and Robinow, 1947; Smith and Trentini, 1972)

Cow dung about two days old is collected from pastures and brought to the laboratory as soon as possible. Samples of 600–800 ml are distributed into beakers and thoroughly mixed with distilled water so that the surface remains covered by a thin layer of water. The beakers are covered with aluminum foil. After 16–24 h of incubation at room temperature, top slurry material is viewed under the microscope for the typical, actively motile *Caryophanon* trichomes and trichome chains.

Attempts at isolation should be made only on samples in which, at a magnification of 400×, *C. latum* occurs in numbers of at least three to four trichomes or trichome-chains per microscopic field. More concentrated samples with up to 20–30 trichomes per field may also be observed.

For isolation, plates may be inoculated directly from this surface material. More enhanced isolation may be achieved by removing as far as possible larger and smaller particles from the slurry such as plant material, protozoa, bacteria, and bacterial and fungal spores. It is necessary to combine several filtration and centrifugation steps:

Isolation Procedure

Skim off the top slurry material from samples with high numbers of trichomes and filter it through coarse filter paper (e.g.) coffee filter paper) to remove large particles (very small pores would soon be clogged by the very fine dung particles). Rinse the solid matter trapped by the filter paper with about 10 ml distilled water and filter again by squeezing it gently.

Centrifuge the combined filtrate using a rotor with approximately r = 15 cm at 1500 rpm. Under these conditions the relatively large trichomes will sediment in about 5 min. Discard the supernatant which includes a large proportion of the fine material. Resuspend the pellet in nutrient broth and repeat the filtration, centrifugation, and resuspension steps once or more.

By applying vacuum, filter the suspension through a membrane filter of about 8-μm pore diameter while adding repeatedly about 20 ml nutrient broth to a total amount of 400 ml. Take care to keep the filter moist throughout this procedure to prevent injury to the trichomes from drying. Remove the membrane filter and agitate it thoroughly along with 2 ml nutrient broth in a flask to wash off the adherent trichomes.

From the final suspension, prepare 10^{-2} to 10^{-5} dilutions and spread 0.1 ml of each dilution on cow dung agar plates containing 80 μg/ml streptomycin.

Cow Dung Agar (Smith and Trentini, 1972)

Cow dung	250 ml
Distilled water	750 ml
Agar	15 g

Mix fresh cow dung with distilled water for 2–3 min in a laboratory mixer to break up large dung particles and ensure thorough dispersion. Add additional water up to I liter and sterilize the medium for 20 min at 121°C. 10 ml of filter-sterilized streptomycin solution (0.8 g per 100 ml) is added after heat sterilization of the medium.

After incubation at room temperature for 48 h, typical colonies of *Caryophanon* colonies may develop. To obtain pure cultures, suspended material from single colonies is repeatedly restreaked onto cow dung agar with or without streptomycin.

Cultivation

Growth of *Caryophanon* strains is good on cow dung agar described above without the addition of streptomycin. Several semisynthetic media have been described for *C. latum* (Pringsheim and Robinow, 1947; Provost and Doetsch, 1962; Kele and McCoy, 1971; Smith and Trentini, 1973). However, they are all not as good as cow dung agar with respect to doubling time and maintenance of the original morphology.

Cultures usually grow best at room temperature or 25°C at a pH of 7.8–8.5. Moran and Whitter (1976), however, stated that 35°C is the optimal temperature for growth of *C. latum*, based upon the rate of change in colony diameter on a given medium.

Maintenance and Preservation

Active cultures of both *Caryophanon* species may be kept at 4–10°C on agar slants for more than 4–6 weeks if protected from drying. Cultures are readily preserved by standard techniques such as freezing in liquid nitrogen or lyophilization.

Cultural and Microscopic Appearance

Colonies of *C. latum* are pale yellow, about 1.5 mm in diameter, opaque, granular, lobate, and show a glistening surface after growth for 48 h on cow dung agar or cow dung agar containing 0.5% lactalbumin hydrolysate at room temperature. Colonies of *C. tenue* are similar to those of *C. latum* in overall appearance, except that they are only 0.5–1.0 mm in diameter and less irregular in shape under the same conditions.

Trichomes of *C. latum* are about 3 μm in width, and 10–20 μm in length. They are straight or slightly curved. Trichome chains may be formed especially in enrichment cultures. They contain two to six trichomes. Individual cells within a trichome are wider than they are long, and several growing septa at various stages of closure can be observed at the same time in each cell.

The size and shape of the organism vary with the culture conditions. As growth proceeds, transverse fissions may give rise to even-shorter, and even spherical, forms. Size frequently diminishes during laboratory cultivation, so that eventually most of the trichomes in a culture may not exceed 1 μm in diameter.

Trichomes of *C. tenue* are about 1.5 μm in width, 10–20 μm in length, straight or slightly curved, and are composed of fewer cells than the trichomes of *C. latum*. Individual cells within a trichome are longer than wide. Only one cross septum can be observed per single cell (Peshkov and Marek, 1973), which may be explained by the much slower growth of *C. tenue* in comparison to *C. latum*.

Caryophanon trichomes are Gram-positive, peritrichously flagellated, and show no branching. Their ends are round or slightly tapered. Under optimal growth conditions, individual cells exhibit a disk-like shape. Cross walls between cells show as dark lines, partly complete, partly developing by ingrowth from the external wall. Endospores, sheaths, and capsules are not formed.

In old cultures or under growth conditions which lead to extensive lysis, a small number of cell units is preserved as round bodies (spheroids). The significance of the spheroids is unknown but it has been suggested that they are part of a "life cycle" (Peshkov, 1939). Under good growth conditions, the spheroids are said to be able to grow into normal trichomes. It should be noted here that almost all investigations have been carried out with *Caryophanon latum*, the morphology of which is strikingly sensitive to growth conditions.

Morphology and motility of *Caryophanon* are difficult to maintain. Both characteristics are reported to be best preserved when 0.5 to 1% lactalbumin hydrolysate is added to cow dung medium. The most authentic morphology and motility of the trichomes, though, can still be observed in enrichment cultures. Optimal growth conditions that will maintain natural trichome morphology as well as mass or colony diameter increase in pure cultures have still to be developed.

Ultrastructure

In cells of *C. latum*, one or two superficial wall layers containing protein are present (Trentini and Gilleland, 1974). Mesosomes, nucleidosomes, and analogs of mitochondria were described by Shadrina et al. (1982).

Chemotaxonomy

Diaminopimelic acid is absent in *C. latum* (Becker et al., 1967). The peptidoglycan of the cell wall is composed of glutamic acid, alanine, lysine, and muramic acid in a molar ratio of $2:2:1:1$. Wall material is sensitive to lysozyme (Trentini and Murray, 1975). Teichoic acids and *O*-acetyl groups are absent (W. Trentini, unpublished observations).

Genetic and Phylogenetic Relationships

Thirty-six strains of *C. latum* isolated from various geographic regions exhibit GC contents of 44.0–45.6 mol% DNA-DNA hybridization studies reveal—with a homology of 78–92%—a high homogeneity among the strains (Adcock et al., 1976). The genome size is $1,100–1,200 \times 10^6$ dalton.

Three strains of *C. tenue* examined for GC content exhibit values of 41.2–41.6 mol% (Adcock et al. 1976). The genome size is $900–1,000 \times 10^6$ dalton. DNA-DNA reassociation studies between *C. tenue* and *C. latum* revealed low homology values of 13–30%.

A close phylogenetic relationship of *Caryophanon* to members of the genus *Bacillus*, in particular to the spherical sporeforming *Bacillus* species, has been described by Stackebrandt et al. (1987). In a dendrogram based on rRNA sequencing studies, the closest relative of *Caryophanon* was *Bacillus sphaericus*. In the same cluster were found *Planococcus citreus*, *Filibacter limicola*, and *Sporosarcina ureae*, as

well as other spherical sporeforming *Bacillus* species.

Physiological and Biochemical Properties

Studies on physiological and biochemical properties of the two *Caryophanon* species have been published mainly by Pringsheim and Robinow (1947), Provost and Doetsch (1962), and Adcock et al. (1976).

Both species are strict aerobes. Catalase is formed. The cytochrome-oxidase reaction is negative. Nutrition is chemoorganotrophic. Starch, gelatin, casein, and cellulose are not hydrolyzed, and indole is not produced. Acetate is used as a major carbon source. More recent studies (Rowenhagen, 1987) revealed that a number of other fatty acids (e.g.) butyrate, valerate, capronate, stearate, methylpropionate, and 2-methylbutyrate) are oxidized by most *Caryophanon* strains. Biotin has been found to be essential for growth, and thiamine seems to be stimulatory.

Strains of *C. latum* were shown not to degrade uric acid or urea and not to utilize glucose and other sugars. Poly-β-hydroxybutyrate is used as a carbon source. Tributyrin is only very weakly hydrolyzed. Nitrates are not reduced to nitrites. These organisms grow at 10 and 37°C but not at 45°C and at pH values between 6 and 8, with an optimum at pH 7.6–8 (Weeks and Kelley, 1958).

For both species, no information has been published on the major metabolic pathways, genetics, or antigenic structure. In almost all cultures with an unbalanced nutrition (e.g., older cultures) poly-β-hydroxybutyrate accumulates. *Caryophanon* strains are resistant to streptomycin, nalidixic acid, several sulfa drugs, and polymyxin B.

Drozd et al. (1987) described a case of concrete corrosion caused by a *Caryophanon* species.

Identification

The genus and the two recognized species can only be identified mainly through their morphological properties (Table 6).

A species-specific phage for *C. tenue* has been described (Peshkov et al., 1973; Peshkov et al., 1966).

Table 6. Differentiating properties of *C. latum* and *C. tenue*.

Character	C. latum	C. tenue
Trichome width (μm)	2.8–3.2	1.4–2.0
Number of cross septa/cell unit	several	1
GC content (mol%)	44.0–45.6	41.2–41.6
Genome size (×10⁶ dalton)	1,100–1,200	900–1,000

CHAPTER 1.2.20

An Introduction to the Family Clostridiaceae

JUERGEN WIEGEL, RALPH TANNER AND FRED A. RAINEY

Introduction

The pre-16S rRNA sequence definition of the genus *Clostridium* was—non-sulfate-reducing sporeformer relying obligately on anaerobic energy metabolism and with a Gram-positive type cell wall (Hippe et al., 1992). Our view of bacterial classification has greatly changed in the past 10 years. We now define the overall taxonomic structure of the prokaryotes, for the most part, on the basis of relationships revealed by comparison of 16S rRNA gene sequences. This has lead to transferring many former clostridial species to novel genera and to a more narrow definition of the genus *Clostridium* (further referred to as *Clostridium* sensu stricto), encompassing much fewer species but including the majority of the medically important species.

Phylogeny

The recent release of the second edition of *Bergey's Manual of Systematic Bacteriology* takes the bold step of proposing a taxonomic structure for all validly described prokaryotes on the basis of a 16S rRNA gene sequence phylogeny. This taxonomic structure in the form of Bergey's Taxonomic Outline is available {online}. Such a structure provides a backbone for a classification system that can be added to as new taxa are discovered and described or can be used to identify taxa that are misplaced. The family Clostridiaceae as defined by the taxonomic outline of *Bergey's Manual of Systematic Bacteriology* contains as its core the genus *Clostridium* (sensu stricto), as well as *Acetivibrio*, *Acidaminobacter*, *Alkaliphilus*, *Anaerobacter*, *Caloramator*, *Caloranaerobacter*, *Coprobacillus*, *Dorea*, *Natronincola*, *Oxobacter*, *Sarcina*, *Sporobacter*, *Thermobrachium*, *Thermohalobacter* and *Tindallia*. The previous inclusion of these additional genera in a family Clostridiaceae is based for the most part on the fact that the type species of these genera are in many cases phylogenetically related to misclassified species of the genus *Clostridium*. However

with the exception of *Anaerobacter*, *Caloramator*, *Oxobacter*, *Sarcina* and *Thermobrachium*, these genera fall outside the radiation of what can be considered the true family Clostridiaceae and are now regarded as belonging to other families within the low G + C Gram-positive phylum. This misclassification is the result of well-known problems of the current taxonomic structure of the traditional genus *Clostridium*. The phylogenetic analysis of Collins et al. (1994) was the first large-scale comparison of 16S rRNA gene sequences of species of the genus *Clostridium* and related taxa. The fact that the species of the genus *Clostridium* did not form a monophyletic group has been shown in a number of studies in which small groups of *Clostridium* species had been compared as far back as 1981 (Tanner et al., 1981; Hutson et al., 1993; Lawson et al., 1993; Rainey and Stackebrandt, 1993a; Rainey et al., 1993b; Willems and Collins, 1994). The comparative study of Collins et al. (1994) and subsequent studies (Stackebrandt and Rainey, 1997; Stackebrandt et al., 1999) can be used to conclude that more than half of the species currently assigned to the genus *Clostridium* are in fact not closely related to the type species of the genus, *C. butryicum,* and from a phylogenetic standpoint should not be included in a newly defined genus *Clostridium*. This extensive genetic diversity of the genus *Clostridium* had been shown using 23S rRNA:DNA hybridization studies back in 1975 by Johnson and Francis (1975), but it was the 16S rRNA gene sequence approach that revealed the actual phylogenetic relationships between the species of this genus and other genera.

There are two main issues that affect the taxonomy of the genus *Clostridium* and related taxa and their allocation to a genus or family within the 16S rRNA-based phylogenetic structure of the Bacteria. Firstly, the genus *Clostridium* current comprises 152 validly described species (see the List of Bacterial Names with Standing in Nomenclature (http://www.bacterio.net). However, on the basis of 16S rRNA gene sequence analyses, only 73 of these validly described species fall within the radiation of the

type species of the genus *Clostridium*, *C. butyricum*, and the cluster I as defined by Collins et al. (1994) (Table 1; Fig. 1). We will refer hereafter to this cluster I as the genus *Clostridium* sensu stricto. The remaining species fall into various phylogenetic clusters throughout the low G + C Gram-positive phylum (Table 2). These 16S rRNA gene sequence based clusters (Collins et al., 1994) can be correlated with the Bergey's Taxonomic Outline to provide a family or proposed family placement for each of the validly described *Clostridium* species (Table 2). The second issue related to the fact that the genus *Clostridium* (sensu stricto, cluster I) has members of other valid genera and in two cases the type species of

a validly described genus clustering within its radiation. The genera that have species that fall within the genus *Clostridium* (sensu stricto) are *Anaerobacter* (*A. polyendosporus*), *Eubacterium* (including *E. moniliforme* and *E. tarantellae*) and *Sarcina* (*S. ventriculi* and *S. maxima*). The position of these taxa within the genus *Clostridium* sensu stricto is shown in Fig. 1.

In the case of the *Eubacterium* species these taxa are misclassified and were placed in the genus *Eubacterium* on the basis of the characteristic that endospore formation was not observed. The genus *Anaerobacter* was described before 16S rRNA gene sequences were available, but this organism does form endospores and has all of the characteristics that would warrant its transfer to the genus *Clostridium* sensu stricto. As first reported by Willems and Collins (1994), both species of the genus *Sarcina* fall within the genus *Clostridium* sensu stricto and in fact are more closely related to the type species of the genus *Clostridium*, *C. butyricum*, than are many of the other *Clostridium* species. This situation is more complicated than that of the *Eubacterium* and *Anaerobacter* species that can be reclassified, in that the genus *Sarcina* was in fact described before the genus *Clostridium* and so has taxonomic priority. However, considering the importance of many of the species of the genus *Clostridium* in animal and human health, the priority is overlooked in this case and both genera retain their original names.

Both of these situations that contribute to the taxonomic disorder of the genus *Clostridium* are due to classification of new isolates for the most part on the basis of phenotypic characteristics, e.g., Gram-positive staining, anaerobic growth, and endospore formation. If a Gram-type or Gram-positive staining organism formed endospores and grew anaerobically, it was added to the genus *Clostridium* and designated a new species in earlier times on the basis of some unique physiological property. This system has continued even when 16S rRNA gene sequences have been determined for new isolates, and it is clear that the new isolates are not members of the genus *Clostridium* in that they fall outside of cluster I (Collins et al., 1994) and are more closely related to other genera than to the type species of the genus *Clostridium* sensu stricto. In many cases these new isolates, although not showing a close phylogenetic relationship to cluster I *Clostridium* species do group with misclassified *Clostridium* species that in fact belong to families other than the family Clostridiaceae. A good example of this is the *Clostridium* species of cluster XIVa. Many of these are polysaccharolytic, cluster together on the basis of 16S rRNA gene sequence analyses, but are unrelated to the clustered of *Clostridium* sensu stricto species. As

Table 1. The species belonging to the genus *Clostridium* sensu stricto (cluster I).[a]

Cluster I species	Cluster I species

[a]According to Collins et al. (1994) and subsequent publications describing new *Clostridium* species.
Fig. 1. Phylogenetic dendrogram showing the relationships between the genera and species of the family Clostridiaceae. The phylogenetic dendrogram was reconstructed from evolutionary distances by the neighbor-joining method using the PHYLIP software package (Felsenstein, 1993). The scale bar represents 5 inferred nucleotide changes per 100 nucleotides. Taxa in red represent valid genera that fall within the radiation of the genus *Clostridium* sensu stricto. The type species of the genus *Clostridium*, i.e., *Clostridium butyricum*, is indicated in green.

Table 2. The species of the genus *Clostridium* that fall outside of the genus (cluster I).[a]

Cluster III represents a new family	*C. aminophilum*
C. aldrichii	*C. aminovalericum*
C. cellobioparum	*C. celerecrescens*
C. cellulolyticum	*C. clostridioforme*
C. hungatei	*C. coccoides*
C. josui	*C. fimetarium*
C. papyrosolvens	*C. hathewayi*
C. stercorarium	*C. herbivorans*
C. termitidis	*C. hylemonae*
C. thermocellum	*C. indolis*
C. thermolacticum	*C. leptum*
Acetivibrio cellulolyticus	*C. litorale*
Bacteroides cellulosolvens	*C. lituseburense*
Cluster IV is within the proposed family "Lachnospiraceae"	*C. methoxybenzovorans*
C. cellulose	*C. methylpentosum*
C. leptum	*C. nexile*
C. orbiscindens	*C. oroticum*
C. sporosphaeroides	*C. phytofermentans*
C. viride	*C. polysaccharolyticum*
Ruminococcus bromii	*C. populeti*
Cluster XIa is within the proposed "Peptostreptococcaceae"	*C. proteoclasticum*
C. bifermentans	*C. saccharolyticum*
C. difficile	*C. scindens*
C. ghonii	*C. sphenoides*
C. glycolicum	*C. sporosphaeroides*
C. hiranonis	*C. symbiosum*
C. irregulare	*C. xylanolyticum*
C. litorale	*C. xylanovorans*
C. lituseburense	**Cluster XIVb is within the proposed "Lachnospiraceae"**
C. mangenotii	*C. colinum*
C. mayombei	*C. lactatifermentans*
C. paradoxum	*C. lentocellum*
C. sordellii	*C. neopropionicum*
C. sticklandii	*C. piliforme*
C. thermoalcaliphilum	*C. propionicum*
Eubacterium acidaminophilum	*Eubacterium yurii*
Peptostreptococcus anaerobius	"*Epulopiscium*" species
Cluster XIb is within the proposed "Peptostreptococcaceae"	**Cluster XVI is a new family**
C. felsineum	*C. innocuum*
C. formicaceticum	*Eubacterium biforme*
C. halophilum	*Eubacterium cylindroids*
Filifactor villosus	*Eubacterium dolichum*
Cluster XII is within the proposed "Peptostreptococcaceae"	*Eubacterium tortuosum*
C. acidurici	*Eubacterium pleomorphus*
C. hastiforme	**Cluster XVIII is a new family**
C. purinilyticum	*C. cocleatum*
C. ultunense	*C. ramosum*
Eubacterium angustum	*C. spiroforme*
Eubacterium thermomarinus	**Cluster XIX is within the proposed "Fusobacteriaceae"**
Tissierella species	*C. rectum*
Cluster XIVa is within the proposed "Lachnospiraceae"	*Fusobacterium nucleatum*
C. aerotolerans	*Leptotrichia buccalis*
C. algidixylanolyticum	*Propionigenium modestum*

[a]As defined by Collins et al. (1994). The family designations of these species based on the cluster placement within the Bergey's Taxonomic outline is provided as well as examples of valid genera within these clusters.

new species are isolated and described in this cluster XIVa, they have been assigned to the genus *Clostridium*, further adding to the taxonomic disorder of the genus.

The *Clostridium* sensu stricto species, the group considered to be the true genus *Clostridium* owing to the presence of the type species *C. butyricum* within this group, represent a phylogenetically diverse group with 16S rRNA gene sequence similarities in the range 92% (the most distant relationships) to >99% (closely related species; Table 1). Within cluster I, the species *C. botulinum* is found dispersed throughout, as shown previously by Hutson et al. (1993) (Fig. 1). The type strain of *C. botulinum*, ATCC 25763T (L37585) groups with *C. sporogenes* and *C. putrificum* (invalid name) and is rather distantly related to other strains bearing the *C. botulinum* species epithet (Fig. 1). At the level of the family Clostridiaceae, including the genera *Caloramator*, *Oxobacter* and *Thermobranchium*, which fall outside of genus *Clostridium* sensu stricto, the 16S rRNA gene sequence similarities range from 89% to >99%. Note that in previous studies, including Collins et al. (1994), the species *C. histolyticum*, *C. limosum* and *C. proteolyticum* grouped outside of this cluster and were assigned to cluster II. As new species have been added to these and the outgroup clusters, the topology of the reconstructed trees have changed somewhat and the distinct separation of the cluster II species from those of cluster I (*Clostridium* sensu stricto) is becoming less clear. There is still however a clear separation of clusters I and II from the other genera of the family that lie outside of cluster I (Fig. 1). Stackebrandt and Rainey (1997) divided cluster I into subclusters Ia through Ii on the basis of the phylogenetic grouping evident within cluster I at the time of that analysis. As new species have been added to cluster I the topology of the subclusters has changed in some cases, and so it seems that redefining the designations of subclusters at this time does not improve the taxonomy of the genus *Clostridium*.

The genera that group outside of *Clostridium* sensu stricto but from a 16S rRNA gene sequence phylogeny perspective fall within the family Clostridiaceae have either been *Clostridium* species transferred to new genera (in the case of *Clostridium fervidum* going to the genus *Caloramator* as *Caloramator fervidus* [Collins et al., 1994] and *Clostridium pfennigii* transferred to *Oxobacter* as *Oxobacter pfennigii* [Collins et al., 1994]) or to newly described genera in the case of *Thermobrachium,* a very close relative of *Caloramator* (Engle et al., 1996).

Other species of the genus *Clostridium* have been transferred from the genus to new genera on the basis of 16S rRNA gene sequence com-

parisons that have shown them to fall outside the radiation of the genus *Clostridium* sensu stricto and outside the family Clostridiaceae. These include *Clostridium* barkeri → *Eubacterium barkeri* (Collins et al., 1994), *Clostridium bryantii* → *Syntrophospora bryantii* (Zhao et al., 1990), *Clostridium durum* → *Paenibacillus durus* (Collins et al., 1994), *Clostridium hydroxybenzoicum* → *Sedimentibacter hydroxybenzoicus* (Breitenstein et al., 2002), *Clostridium lortetii* → *Sporohalobacter loretii* (Oren et al., 1988), *Clostridium oxalicum* → *Oxalophagus oxalicus* (Collins et al., 1994), *Clostridium quercicolum* → *Dendrosporobacter quercicolus* (Strompl et al., 2000), *Clostridium thermaceticum* → *Moorella thermacetica* (Collins et al., 1994), *Clostridium thermautotrophicum* → *Moorella thermautotrophica* (Collins et al., 1994), *Clostridium thermocopriae* → *Thermoanaerobacter thermocopriae* (Collins et al., 1994), *Clostridium thermohydrosulfuricum* → *Thermoanaerobacter thermohydrosulfuricus* (Lee et al., 1993), *Clostridium thermosaccharolyticum* → *Thermoanaerobacterium thermosaccharolyticum* (Collins et al., 1994), *Clostridium thermosulfurigenes* → *Thermoanaerobacterium thermosulfurigenes* (Lee et al., 1993), and *Clostridium* villosum → *Filifactor villosus* (Collins et al., 1994).

As indicated above, the majority of the species currently assigned to the genus *Clostridium* fall outside the genus as defined by Collins et al. (1994) and outside the family Clostridiaceae. Table 2 indicates the families to which these *Clostridium* species, which we should consider as incertae sedis at this time, might be allocated on the basis of their association with other genera and species. Collins et al. (1994) not only designated these species to clusters II through XVIII but indicated that they might represent taxa at family levels, families that they designated 1 through 13. The taxonomic outline as presented by Bergey's Manual® allows for the placement of each of these misclassified *Clostridium* species in a family. This provides the basis for a reclassification of these species to existing genera within these families or the description of new genera. Table 2 shows the family affiliation for each of the *Clostridium* species that fall outside of the genus *Clostridium* sensu stricto (cluster I).

Habitats

The habitats and ecology of the type species of *Clostridium* (Cato et al., 1986), *Clostridium butyricum*, is representative for many species in this family. *Clostridium butyricum* is a mesophilic, Gram-positive staining, sporeforming anaerobe found in soil, sediments, the rumen,

and even in the decaying heartwood of living trees. The anaerobic nature of this bacterium (or a close relative) was first noted by Pasteur in his description of "vibrion butyrique" (Pasteur, 1861). Like a number of other mesophilic clostridia and related bacteria found in soil, *C. butyricum* has been recovered from wounds and abscesses, but it is not a pathogen in the same sense as *Clostridium perfringens* or *Clostridium tetani*. *Clostridium butyricum* can fix nitrogen, as do a number of other clostridia. The ability to fix nitrogen is probably more widespread in the Clostridiaceae than currently appreciated. The metabolism of *C. butyricum* is primarily saccharolytic, as it is for the majority of the described species of Clostridiaceae.

Because of the nature of forming spores, generally clostridia and related species can be isolated from nearly every environment including melted snow or ice from Antarctica, dry desert sand, alkaline and acidic hot spring water and mud, mesobiotic and psychrobiotic river and lake water or sediments, and intestinal tracts of animals and insects. Thus clostridia as a group are truly ubiquitous. Even pathogenic clostridia including *C. botulinum* and *C. tetani* can be isolated from nearly every aerobic soil sample and dust, a reason that both are still important pathogens despite available immunization against *C. tetani*. Also, clostridia have been isolated from feces since their spores can stay viable when passing through intestinal tracts.

However, when dealing with habitat questions one has to keep in mind that because of the presence of nongrowing spores, isolation of clostridia and related bacteria from an environment or the presence of a corresponding 16S rRNA gene sequence, does not indicate that the isolates or the corresponding bacteria grew or were able to grow and multiply in that environment. A first estimate of whether a specific species could grow and multiply in a given environment can be made by comparing the known or freshly tested physiological properties of the species or isolates in question and the environmental parameters of the sampling place. However, a word of caution has to be made here, in that frequently bulk measurements for environmental samples do not reflect absence of possible growth conditions available in microniches within the given site. Conditions in such microniches can provide on small scales, sometimes only temporarily, significantly different growth conditions (i.e., substrate concentrations, pH, temperature, and other nutrients) than those represented by bulk measurements. One well-documented example is that the high respiratory activity of one or more aerobic bacteria can provide an anaerobic microniche in which obligate anaerobic bacteria could grow, e.g., the oxygen

sensitive N_2-fixing clostridia in aerobic *Bacillus* agar surface colonies as described by Postgate (1974) and Line and Loutit (1973) more than 30 years ago. One way to test whether the bacteria are growing is to compare enumerations (e.g., most probable numbers [MPNs], with extended incubation temperatures to allow spores to germinate) in pasteurized (or in case of thermophiles, heated for 1–5 min at 100ºC) and in untreated samples. Another example is the fast-growing *Thermobrachium celere* from various mesobiotic environments. The doubling times of strains from mesobiotic environments are 10–20 min, whereas the doubling times from strains from hot springs have doubling times above 30 min. *Thermobrachium* is also a moderate alkaliphile (alkalithermophile) that was isolated from environments with bulk pH values below pH 5.0 (Engle et al., 1996; M. Engle and J. Wiegel, unpublished data).

Isolation and Cultivation

The underlying phenotype common to all of the members of the family Clostridiaceae is the anaerobic phenotype. So, anaerobic technique is essential for the enrichment, isolation and culture of members of this group (see Ljungdahl and Wiegel [1986], Hippe et al. [1992], and Tanner [2002]).

Anaerobic Culture Technique

The recommended procedures for current anaerobic technique were developed in the laboratory of Ralph S. Wolfe during the mid-1970s and are generically referred to as "the Balch technique." The Balch technique is based on the Hungate technique, used for many of the seminal advancements in anaerobic microbiology in the 1960s and still used today. For example, roll tubes are still one of the easier ways to manipulate anaerobes on agar surfaces or in agar using the agar-shake-roll tube method (Ljungdahl and Wiegel, 1986; Tanner, 2002). These techniques use specialized user-friendly glassware and equipment to easily manipulate anaerobes or any microorganism requiring a defined gas phase. These procedures will be the focus of the discussion here. Some of the key methodological references for anaerobic microbiology are given in Table 3. Various laboratories working with anaerobes have developed their own modifications depending on preferences or needs.

Simpler approaches to anaerobic microbiology are covered in the literature (Willis, 1969; Hippe et al., 1992), much of it targeted towards medically important clostridia (Sutter et al., 1985) that are in general less sensitive to air or

oxygen than most clostridia. Indeed, the oxygen tolerance of clostridial species ranges from relative insensitivity, such as for *Clostridium aerotolerans* (Van Gylswyk and Van der Toorn, 1987) to extreme sensitivity, such as for some of the hydrogen-oxidizing acetogens (Drake, 1994).

The removal of oxygen and lowering the redox potential of culture media by the addition of a reducing agent are the two crucial parts of the technique. The removal of oxygen is usually achieved by boiling the medium. This will often be done with the medium under a stream of anoxic gas (Bryant, 1972) for a small batch of medium, or by steam sterilization in an autoclave for a large batch (above 1–2 liters). Steam sterilization is done with the vessel covered but still open to the atmosphere. After autoclaving, the medium is cooled under a stream of sterile, anoxic gas (Hungate, 1969), then sealed (Balch et al., 1979). Finally, sterile reducing agent is added to reduce the medium's redox potential. For preparing or dispensing anaerobic media in small batches such as in various tubes or serum bottles, the media are made anoxic by boiling, cooled to below 40°C, reduced by adding the appropriate amount of reducing agent, and then under the stream of oxygen-free gas, distributed into the tubes or bottles, which then are sealed with stoppers and aluminum crimps and autoclaved. In laboratories dealing with a lot of soil samples or various sporeforming strains, autoclaving time at 121°C should be extended to 30–40 min to ensure that heat resistant spores are killed (see the discussion of spore stability, especially of thermophilic clostridia and related species). In some instances, autoclaving the media a second time after incubating for 36–48 h at 30°C or 60°C is recommended for laboratories primarily working with thermophiles and thermobiotic soils and sediments.

A good grade of compressed gas, such as prepurified grade or better, is the starting point for provision of anoxic atmospheres. The gas is scrubbed free of oxygen in a heavy-walled copper tube (2.5×20–30 cm) packed with copper turnings and heated to 150–200°C in a tube furnace or with heating tape. Periodic exposure of this scrubber to hydrogen will readily regenerate the system. Sterile gas can be obtained by passing it through self-made gas filters, constructed from 2-ml glass syringe barrels with luer lock tips and packed with nonabsorbent cotton. Stainless steel needles, 17 gauge, complete the probe. These will tolerate many flame sterilizations, are small enough to be used with stoppered glassware without chipping it, but have a large enough bore for flushing syringes prior to making anoxic transfers.

A good anaerobic chamber equipped with an air lock greatly facilitates preparation of materials for anaerobic microbiology. The flexible chambers from Coy Laboratory Products, Inc. (Grass Lake, Michigan, United States) are economical and the easiest to use and maintain. The advantage of the anaerobic chamber is that it allows anaerobes and media to be handled as if they were on an open bench, facilitating plate transfers, dispensing of media, etc. Our chambers are operated with a gas phase of 1–2% hydrogen in nitrogen; oxygen levels of 2 parts per million (ppm) or lower (as measured by a palladium hydrogen probe) are easily achieved. The inclusion of activated charcoal gas scrubbers (to adsorb H_2S which poisons the catalyst) and an agent to remove moisture from the atmosphere (anhydrous calcium chloride pellets, 4–20 mesh) facilitate chamber and chamber catalyst (palladium on alumina pellets) maintenance. An anoxic solution of 1 N hydrochloric acid is used to clean and disinfect the anaerobic chamber.

This leaves no residue and its vapors are absorbed by the calcium chloride drying agent. Chambers seem to be easier to maintain if they are not used for culture incubations. The polyvinyl chloride (PVC) flexible bags of the chambers last more than 10 years, even with daily use. The use of ultraviolet (UV)-lamps for sterilization overnight or weekends is not recommended since it shortens drastically the life of the plastic bag.

A gas exchange station (Balch and Wolfe, 1976) allows control over the final atmosphere used for tube or plate culture of anaerobes. Elimination of as many joints and valves as possible, as well as construction from stainless steel components, simplifies the use and maintenance of a gas exchange station.

The use of a reducing agent to lower the redox potential of medium after the removal of oxygen is important for the culture of anaerobic bacteria. A variety of reducing agents are available, many based on sulfur chemistry (Hespell, 1990; Tanner, 1997; Tanner, 2002). Sodium sulfide solutions are commonly used. The authors use mainly cysteine-sulfide solution for most of their routine culture work. Cysteine (4 grams; free cysteine, not cysteine hydrochloride or another acid adduct) and anoxic water (boiled under an oxygen-free gas, then stoppered) are placed in an anaerobic chamber overnight. Sodium sulfide nonahydrate crystals (4 grams, freshly washed and dried) are taken into the chamber and dissolved with the cysteine in 100 ml of water. This is dispensed and stored in sealed tubes. For most media, 0.1–0.5 ml of this reducing agent is added per 100 ml of degassed medium taken into an anaerobic chamber for dispensing prior to sterilization. This reducing agent (prepared as just described) is stable for over a year.

General Medium Preparation

A general basal culture medium and the composition of stock solutions used to prepare it are given in Tables 4–7 (Tanner, 1997; Tanner, 2002). There are a number of other formulations of mineral, vitamin and metal stock solutions, many of which may be found in the *Handbook of Microbiological Media* by Atlas and Parks (1997). The desired carbon source, energy source, and electron acceptor, if any, are added to this basal medium for enrichment, isolation and culture of desired cell types. Attention to the type of microbial metabolism desired will indicate modification of this or any other basal medium recipe. For example, if a nitrogen-fixer were desired, ammonium salts would be eliminated from the medium. If strict control of any potential sulfate-reducing bacteria were required, chloride salts would be substituted for

Table 4. Basal medium.[a]

Component	Amount per liter
Mineral solution[b]	10 ml
Vitamin solution[c]	10 ml
Trace metal solution[d]	5 ml
Buffer[e]	2–10 g
Adjust pH as required	

[a]A general purpose medium adapted to pure culture or environmental studies upon the addition of the electron acceptor, electron donor and carbon source desired. A general source of growth factors, such as yeast extract (0.05–0.1 grams per liter), is often included.
[b]Described in Table 5.
[c]Described in Table 6.
[d]Described in Table 7.
[e]Good's buffers are recommended (Good et al., 1966). *N*-Tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid (TES) should be used for neutral pHs, morpholinoethane sulfonic acid (MES) for slightly acidic pHs, and *N*-tris(hydroxymethyl)methyl-3-aminopropanesulfonic acid (TAPS) for slightly alkaline pHs. Bicarbonate needed to balance carbon dioxide in the gas phase should be added after pH adjustment of the medium.

Table 5. Mineral solution.[a]

Component	Amount in grams per liter
NaCl	80
NH_4Cl	100
KCl	10
KH_2PO_4	10
$MgSO_4 \cdot 7H_2O$	20
$CaCl_2 \cdot 2H_2O$	4

[a]Adapted from Balch et al. (1979). Modified to reduce the number of required stock solutions. Includes calcium, which is often found in trace metal solutions.

Table 6. Vitamin solution.[a]

Component	Amount in mg per liter
Pyridoxine · HCl	10
Thiamine · HCl	5
Riboflavin	5
Calcium pantothenate	5
Thioctic acid	5
p-Aminobenzoic acid	5
Nicotinic acid	5
Vitamin B_{12}	5
MESA[b]	5
Biotin	2
Folic acid	2

[a]Adapted from Wolin et al. (1963). Includes a higher level of B_{12} compared to other vitamin solutions.
[b]Mercaptoethanesulfonic acid added for cultivation of the methanogenic archaea.

Table 7. Trace metal solution.[a]

Component	Amount in grams per liter
Nitrilotriacetic acid adjust pH to 6 with KOH	2.0
$MnSO_4 \cdot H_2O$	1.0
$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$	0.8
$CoCl_2 \cdot 6H_2O$	0.2
$ZnSO_4 \cdot 7H_2O$	0.2
$CuCl_2 \cdot 2H_2O$	0.02
$NiCl_2 \cdot 6H_2O$	0.02
$Na_2MoO_4 \cdot 2H_2O$	0.02
Na_2SeO_4	0.02
Na_2WO_4	0.02

[a]Adapted from Wolin et al. (1963). Modifications based on findings in the biochemistry of anaerobes. Other trace metal solutions often contain a source of boron and aluminum, as well.

any of the sulfate salts in the recipes. The growth of many anaerobes, even those that produce significant amounts of CO_2 as an end product, is stimulated by the presence of CO_2 in the gas phase. This CO_2 must be balanced by bicarbonate or carbonate to achieve the desired culture pH. In general, more bicarbonate is needed when the pH, incubation temperature, and partial pressure of CO_2 in the gas phase is higher. For example, to culture medium at pH 7.0 and in 20% CO_2 at a gauge pressure of 200 kPa, 2 and 4 grams of sodium bicarbonate per liter are added for incubation at 37°C and 60°C, respectively. For cultivation at pH of 6.0 or lower, bicarbonate additions can be omitted (this pH is outside of the bicarbonate/CO_2 buffer range). An advantage of using a gas phase that contains 10–30% CO_2 is that the amount of bicarbonate needed in the medium is small so that the bicarbonate can be sterilized as part of the whole medium. If a 100% CO_2 atmosphere is used, addition of bicarbonate or carbonate from a sterile stock solution to the medium is often necessary after steam sterilization to avoid precipitation or other problems. Bicarbonate is not stable above 50°C and forms CO_2 and carbonate. At concentrations above 1% the resulting CO_2 pressure can burst the culture vessels. Thus when elevated concentrations are needed, sodium carbonate can be used instead of bicarbonate. The pH is then adjusted by appropriate gassing with sterile CO_2 (i.e., passing the gas through cotton filled syringes).

Selection of Sporeforming Clostridia

As discussed above, not all members of the Clostridiaceae readily form spores. The sporeforming clostridia can be selected usually by treating with heat or alcohol (above 70% [v/v]), which kills or inhibits the growth of vegetative cells. Not all spores will survive these treatments and not all vegetative cells will be killed by these treatments, but this approach is still useful. The pasteurization procedure described in Hippe et al., (1992) is a very good example of the use of heat treatment to eliminate vegetative cells. The inoculum and a 0.9% saline blank are placed in an 80°C water bath. The blank has a thermometer to monitor temperature. The samples are held in the water bath for 10 min after 80°C is reached and then immediately cooled to room temperature. The specimens are now ready as inocula for enrichments or direct isolations.

For thermophilic species, the modified procedure of using 100°C for 1–2 min is recommended, which will heat-activate most spores from thermophiles. Some spores require a heat treatment of 100°C for complete activation (Byrer et al., 2000).

Treatment with ethanol is another good way to eliminate vegetative cells from an inoculum (Koransky et al., 1978). Suspended soil, sediment or liquids are mixed with an equal volume of sterile absolute ethanol and then incubated, preferably under anoxic conditions, for 60 min. Samples are now ready for inoculation into enrichments or for direct isolation procedures.

Enrichment and Isolation of Clostridia

In most cases, the numbers of the desired cell type are too small compared to the total number of bacteria for consistent or successful recovery. So, enrichments to increase these numbers need to be done prior to isolation. A combination of both approaches initially can be useful to recover desired clostridia, as often the different approaches will result in the isolation of different species. To illustrate this, consider the isolation of a clostridium that uses methanol as a carbon and energy source. Enrichments would be set up using a basal medium supplemented with a relatively low concentration of substrate (2 grams per liter) and with a relatively high concentration (10 grams per liter). One set of enrichments would receive a large inoculum and one set, a very small inoculum. This inoculum may be a suspension of 1 g of sediment in 10 ml of anoxic buffer. One ml of this suspension into 10 ml of enrichment medium would be a large inoculum and 1–2 drops, a small inoculum. One of the authors frequently uses inocula of 5–8 g (wet wt) or ml of sediment slurries per 100 ml of enrichment. Incubation at different temperatures could be another factor for this enrichment. Enrichment medium would be supplemented with 50 mg of yeast extract (Difco) per liter of medium. Simultaneously, direct isolation of

anaerobic methanol utilizers may be attempted in roll tubes (Hungate, 1969; Bryant, 1972) using medium with 1 g of yeast extract per liter. Again, a small and a large inoculum would be used. In all likelihood, methanol-fermenting bacteria may only appear in enrichments set up with the large inocula. However, the chances are that successful enrichments or isolations established under different initial conditions will yield isolates from different taxonomic groups.

The generalities of enrichment technique, some with emphasis on the clostridia, are summarized in many references, including Ljungdahl and Wiegel (1986), Hespell (1990), Gottschal et al. (1992), Hippe et al. (1992), and Tanner (1997) and Tanner (2002) (Table 3). The primary literature, such as the International Journal of Systematic and Evolutionary Microbiology (IJEM; formerly the International Journal of Systematic Bacteriology, IJSB) and Systematic and Applied Microbiology, should also be utilized routinely.

Some generalities are considered here: The basal medium given in Table 4 is a good starting point for many enrichments and culture media. Substrate is often added at 2–5 g per liter. The addition of yeast extract at 0.05–1 g per liter is often stimulatory, if not required (Adkins et al., 1992; Tanner, 2002). If desired, 5–20 mM electron acceptors (e.g., sulfate) are added. Hydrogen or carbon monoxide can serve as an electron source, and CO_2 as an electron acceptor. The presence of some CO_2 in the gas phase is often stimulatory, if not required. The inclusion of a buffer for pH control is usually recommended.

Undefined or commercially available media, such as cooked meat medium or trypticase soy agar, are generally not used for enrichments, unless one has treated a sample to eliminate vegetative cells and is recovering spores. They are more important for some isolations or standard culture of clostridia. It is not unusual to add significant amounts (2–10 g per liter) of yeast extract, trypticase or other complex nutrient sources for isolation and culture of clostridia.

Individual colonies of clostridia may be isolated from enrichments or directly from environmental samples by plating and incubation in anaerobic plate holders (e.g., Balch et al., 1979), bottle plates (Hermann et al., 1986), or roll tubes (Bryant, 1972). The authors have used all these techniques and have a slight preference for diluting out inocula in cooled, but still liquid (40–45ºC), agar and preparing roll tubes (termed "agar-shake roll tubes"). Subsequently, colonies can be picked for further liquid culture using a 1-ml syringe equipped with a slightly bent 3.8 cm, 20 gauge needle or using autoclaved Pasteur pipettes drawn out at the tip into a capillary and then bent. The colony is stabbed and the agar plug injected into a sealed serum tube

with an appropriate medium. Another isolation technique is to dilute an inoculum into cooled agar and incubate as solid butts. After colonies appear, these agar plugs can be aseptically removed from culture tubes, the colony aseptically exposed, using a syringe (or sterilized Pasteur pipette) and then transferred to a tube of liquid medium. Sealed serum tubes (e.g., no. 2048, Bellco Glass Co., Vineland, NJ, United States; Balch and Wolfe, 1976) or Hungate-type culture tubes (no. 2047, Bellco Glass Co.) are useful for routine culture. Cultures remain viable longer on agar surfaces than in broths especially when grown on mineral media in the presence of slowly metabolizable substrates. Agar slants can be prepared in sealed tubes and a drop of liquid inoculum injected through a stopper onto the top of the slant. This drop can flow down the slant, and growth on the agar surface will appear after incubation. There are a number of ways to prepare cultures of clostridia for long-term storage. One way is to obtain a good spore solution (i.e., a solution of highly refractile spores when examined by microscopy); spores of many species can be kept at 0–7°C for years without losing viability (J. Wiegel, unpublished data). A relatively easy method to maintain vegetative cultures that has been very successful in our hands is storage in glycerol (Wiegel, 1986; Tumbula et al., 1995). Anoxic glycerol (2 ml) is placed in sealed serum vials (10 ml) under a nitrogen gas phase and sterilized. A cell pellet is collected after gentle centrifugation (this can be done directly in sealed serum tubes with the appropriate adapters). The cell pellet is resuspended in 2 ml of either fresh or spent medium and injected into the vial. Stored at –20°C, the cells stay in liquid suspension, so little freeze damage occurs. Cells from as much as 20 ml of broth culture are readily concentrated for this 2 ml addition.

The culture of anaerobic clostridia is relatively easy after a little experience, almost as easy as that of *Escherichia coli* or a pseudomonad. Remember to make use of the general and primary literature as required and make use of experienced colleagues for training and advice.

Identification

Although nowadays most investigators identify their isolates using 16S rRNA sequence data, confirmation through comparison of the various properties of the different species is still important. As pointed out by several investigators, significant differences in morphology and physiology between isolates with very similar small subunit ribosomal RNA sequences (above 99% sequence similarity of the 16S rRNA gene)

can occur and lead to separation into different species.

Morphology

GRAM REACTION AND CELL WALL The phylogenetic branch of the Firmicutes is also called the branch of the "Gram positives" with low DNA mol% G + C, relating to the feature that the majority (see below) of the bacteria from this group stain Gram positive and exhibit a thick murein cell wall called "the Gram-positive cell wall type." Taking into account the above-discussed phylogenetic diversity, it is not surprising that the clostridial branch (Order Clostridiales) is very diverse and not homogenous in either overall morphology or biochemical characteristics of the cell components (Cato et al., 1986; Hippe et al., 1992; Dürre, 2004). On the basis of the 16S rRNA gene sequences, the Clostridiales contains both true Gram-type negative genera as well as those that only stain Gram negative. In fact, quite a large percentage of species among the Clostridiaceae (see species description) stain negative at all growth phases, regardless of the procedural modifications used (Popescu and Doyle, 1996; O'Brien and George, 1997). This includes species of *Clostridium* sensu stricto as well as "clostridia" species from genera no longer belonging to the family Clostridiaceae, e.g., *C. aceticum*, *C. arcticum*, *C. thermocellum* and *C. cellobioparum* (cluster III), *C. quercicolum* (cluster IX, now called "*Dendosporobacter*" within the Peptococcaceae), *C. formicaceticum* (cluster XI), *C. polysaccharolyticum* and *clostridiforme* (cluster XIVa). Thus, this discrepancy is widespread and not restricted to a specific cluster or subbranch of the Clostridiales. In addition, several species *C. tetani* (*Clostridium* sensu stricto) and *C. propionicum* (cluster XIVb) stain Gram negative in the mid to late exponential growth phase, whereas *C. indolus* and *C. puniceum* (*Clostridium* sensu stricto) stain Gram variable (*C. indolis* and *C. puniceum* [*Clostridium* sensu stricto]). To avoid confusion, i.e., including "Gram negative" species in the phylogenetic "Gram positive" branch, Wiegel suggested the term "Gram type" be used when referring to the systematic or phylogenetic position and "Gram staining" or "Gram reaction" when referring to the results of the Gram staining reaction (Wiegel, 1991; Wiegel et al., 1992). These terms will be used in the remainder of this chapter. The 16S rRNA gene sequence-based phylogenetic trees of the genera within the phylum Firmicutes defined as above clearly have to be labeled not only as "Gram-reaction negative" but also as "Gram-type negative," i.e., as genera of bacteria possessing a true Gram-type negative cell wall containing lipopolysaccharide (LPS). Prominent examples include a species from the family Heliobacteriaceae, the genus *Megasphaera* (non-sporulating) and, possibly, *Sporomusa*, the only Gram-type negative endospore former, although the presence of LPS has not been unequivocally demonstrated for the latter. Within the family of the Clostridiaceae, such examples have not been found, yet. Whether some Gram-type positive bacteria have a periplasmic or analogous space is still under discussion (Merchante et al., 1995; Navarre and Schneewind, 1999). The typical cell wall type for several clostridia, including the type species *C. butyricum* and all *Clostridium* sensu stricto species, is the *meso*-DAP direct type (*meso*-diaminopimelic acid is the direct bridging amino acid between the peptidoglycan strands). This type is also typical for the Gram-type negative cell wall. But most other members of the Clostridiaceae and Clostridiales, for which the cell wall has been determined, exhibit various cell wall types differing in the amino acids of the intervening peptide interbridges and side chains. These types are regarded as typical for Gram-type positive cell walls (for details, see Schleifer and Kandler, 1972), and various examples are found within the different clusters of Collins et al. (1994). Although in general, the specific cell wall type is regarded as a taxonomic feature for a genus, there are now exceptions to this. For example, the two alkalithermophiles *Clostridium paradoxum* and *C. thermoalkaliphilum* (cluster XI of Collins et al., 1994) are closely related with about 98% similarity in their 16S rRNA gene sequence. However, *C. paradoxum* contains the *meso*-DAP direct type, whereas *C. thermoalkaliphilum* has the L-ornithine-D-aspartate type (A4ß-type; Li et al., 1993; Li et al., 1994). Even closely related species (i.e., belonging to cluster XI of Collins et al., 1994) *C. formicaceticum* and *C. felsineum* contain *meso*-DAP, whereas *C. villosum* has ornithine-*iso*-D-asparagine, *C. glycolicum* contains no DAP but rather lysine and *iso*-D-asparagine, and *C. lituseburense* contains lysine and aspartic acid (Cato et al., 1986). Until the majority of the clostridial and related species have undergone cell wall analysis, the question of whether the cell wall type is a general taxonomic and systematic character for this group, remains open.

CELL SHAPES AND SIZES Given the heterogeneity of the Firmicutes, it is no surprise that a wide variety of morphological features are observed, although many species of the family Clostridiaceae exhibit typical rod-shaped cells. Many of the morphological descriptions of the long-known species are from Holdeman et al. (1977) and were updated by Moore et al. (1987) who described the anaerobic microorganisms when grown on peptone-yeast extract (PYG-media)

with or without added glucose (PY-media), or on blood or chopped meat agar. These media have become to some extent standard for describing mesophilic anaerobes. The morphology of some clostridial species cultivated on those different media change very little, while others change a lot in their diameter and length.

Most of the species belonging to the genus *Clostridium* sensu stricto and related genera are straight (e.g., *C. tetanomorphum* and *C. subterminale*) to slightly curved (e.g., *C. butyricum*) rods of different lengths and diameters, the ends of which vary from rounded and squared (e.g., *C. anthracis*) to tapered or pointed (e.g., *C. clostridioforme*, *C. perfringens* and *C. spiroforme*). During the exponential growth phase, the rod-shaped cells of most species are 0.5–1.8 μm but can be as thin as 0.3 μm (e.g., *C. sticklandii* and *C. barkeri*), as wide as 2 μm in diameter (*C. subterminale*), and 1.5–5 μm in length. Some species exhibit cells as long as 20 μm (e.g., when sporulating, see below) and even up to nearly 100 μm (e.g., *C. thermobutyricum*) under stress conditions when septation formation is affected. Nearly all Firmicutes species, especially anaerobes, exhibit pleomorphisms although to different degrees. These pleomorphisms include 1) irregular rods (e.g., *C. acetobutylicum*); 2) cells with bulging ends (observed frequently with many lactobacilli, clostridia and thermophilic anaerobes such as *Thermoanaerobacteria* when grown above their growth optimum temperature and under rich media conditions, e.g., the *Clostridium* sensu stricto species *C. palmarium* and *C. thermobutyricum*); 3) cells with true branching (e.g., *Thermobrachium* and *Anaerobranca* but so far not observed among *Clostridium* sensu stricto species); 4) cells forming long chains (e.g., *C. oroticum* → Lachnospiraceae; *C. bifermentans* → "Peptostreptococcaceae"); 5) cell aggregates forming twisted spaghetti-like structures at high pH or high temperature or both (*C. thermobutyricum*); 6) cells forming necklace-like chains with coccoid cells located alternatively between rod-shaped cells (e.g., *Thermoanaerobacter* species), which is due to nonsymmetrically dividing cells; and in connection with spore formation, 7) long filamentous cells (less than half the cell diameter, 3–10 times longer than the regular vegetative cells, e.g., *Clostridium thermocellum* (cluster III of Collins et al., 1994). But the family Clostridiaceae also includes species exhibiting mainly coccoid morphology (e.g., *C. coccoides* → Lachnospiraceae; *C. oceanicum* → *Clostridium* sensu stricto species); vibrio-like, nearly circular ring-shaped cells (e.g., *C. methylpentosum* → Lachnospiraceae; *C. cocleatum* → Collins et al. [1994] cluster XVIIIa; and spiral-shaped cells [e.g., *C. cocleatum* and *C. spiroforme*]).

One of the more obvious exceptions to the rod shaped morphology among the Clostridiaceae are the sarcina (anaerobic packet-forming bacteria). Sarcina-morphology is characterized by the uniquely shaped cell packets of of 4, 8, 12 or 16 and under some conditions larger clumps formed by divisions occurring more or less synchronously in 2 or 3 perpendicular planes, and the dividing cells are usually not separating into individual daughter cells. The "clostridial sarcina" (i.e., in the phylogenetic radius of *Clostridium* sensu stricto) are to be differentiated from the former sarcina, which are now classified in different taxa and some in different domains: the aerobic *Sporosarcina* (Bacillales), the packet-forming, asporogenic *Micrococcus*, the anaerobic *Methanosarcina* (domain Archaea), and the aerobic *Kineococcus* (Phillips et al., 2002). *Sarcina ventriculi* and related isolates are unique among Clostridiaceae because they produce extracellular cellulose fibers that aid in keeping the cells together (Canale-Parola et al., 1961; Canale-Parola, 1970).

COLONY MORPHOLOGY ON ANAEROBIC AGAR PLATES OR ROLL TUBES The colony form depends on whether the cells are grown on surface plates or on or within the agar of agar shake-roll tubes. Some species require a long adaptation and freshly prepared plates to be able to grow on or in agar-, Gelrite-, or Carrageen-solidified media because of their requirement of high water activity. Usually these isolates can be adapted by starting with soft agar and then transferring frequently to solid media containing increased concentrations of the solidifying agent. Many colonies located within the agar are of whitish to brownish color and disc shaped, and depending on gas production, split the agar. On plates, the colonies are round to irregular, raised or flat, translucent to white or brownish, shiny or dull. This morphology frequently depends on the type and age of the media.

FORMATION OF SLIME, CAPSULES AND SHEATHS Firmicutes do not form sheaths such as those formed by the extreme thermophilic Thermotogales or mesophilic leptothrix, nor is excessive slime formation (e.g., the formation of levan by some lactic acid bacteria) a property of species in the family Clostridiaceae. But similar to *Bacillus* and *Lactobacillus* species, several clostridia can form small capsules of various consistency and structure, which can be made visible with the traditional method of India ink using light microscopy. Most of these polysaccharide capsules are heteropolymers frequently containing uronic acids beside amino sugars. An unusual capsule is the one of *Sporosarcina* species (similar to *Bacillus* spe-

cies such as *B. subtilis*, *B. licheniformis* and *B. anthracis*) consisting of γ-polyglutamic acid or a γ-D-glutamyl polymer (Troy, 1973; Kandler et al., 1983). Furthermore, many clostridia, produce slime material when growing in biofilms and on surfaces, e.g., in fermentors during continuous culture of, e.g., *C. thermobutyricum* (Canganella and Wiegel, 1999) or *Morella thermacetica* and *M. thermautotrophica* (Wiegel et al., 1991).

FLAGELLA, PILI AND FILAMENTS Many Firmicutes are peritrichously flagellated. However, in many instances the number of flagella is low (i.e., 3–10). Pili have also been described (e.g., in *Moorella glycerini*; Slobodkin et al., 1997), but for most described species, the occurrence has not been investigated carefully by electron microscopy so it is not clear whether pili occur more rarely in clostridia than in, e.g., proteobacteria or lactic acid bacteria.

An unusual morphological feature is observed with clostridia isolated from acid forest soil. *Clostridium acidisoli*, *C. akagii* (both *Clostridium* sensu stricto species), and *C. uliginosum* form chains or aggregates linked by connecting filaments (each composed of a core and outer sheath) that have no known function (Kühner et al., 2000; Matthies et al., 2001).

STRUCTURES ASSOCIATED WITH EXTRACELLULAR PROTEIN (COMPLEXES) Members of the Clostridiales exhibit several different methods of excreting and attaching various surface proteins to the outer cell wall envelope (for details, see Navarre and Schneewind, 1999).

S-layer The most recognizable among the surface layer proteins are the S-layer proteins, all of which are widespread among the Firmicutes. These self-assembling subunits occur usually in typical geometric arrays on the surface, as observed by electron microscopy. Most arrangements are hexagonal, tetragonal and oblique (Sara and Sleytr, 2000). The pattern is independent of the bacterial cell on which they assemble. Although the pattern of the S-layer proteins is species–specific, they are presently not regarded as genera-specific among the Firmicutes. Several clostridia and related species contain a nongeometrically structured protein layer of enzymes, without any visible regular geometric pattern of proteins or protein-carbohydrate complexes. Some clostridial and related species exhibit extracellular enzymes with S-layer-like sequences and are attached to structures on the outside of the cell wall (Sara, 2001). S-layer sheets have been suggested for use as matrix material to support enzymes (Sleytr et al., 1996).

Structures Associated with Extracellular Protein (Complexes) Some enzymes form special protein complexes or structures on the outer cell envelope (Navarre and Schneewind, 1999). A special configuration of extracellular enzymes has been found in the anaerobic, thermophilic and mesophilic clostridia and related bacteria which are able to hydrolyze crystalline cellulose. The cellulolytic enzymes are excreted as large (4–8 MDa) enzyme complexes called "cellulosomes" (Bayer and Lamed, 1986) containing various cellulases, xylanases and esterases (e.g., feruloylesterase, which cleaves the cellulosic strands from lignin [Bayer et al., 1994; Doi et al., 2003; Madkour and Mayer, 2003] and forms polycellusomes [Mayer et al., 1987]). Correspondingly, xylosomes associated with xylanolytic anaerobes have been proposed but not yet unequivocally demonstrated for any low G + C Gram-positive strains. However, for several of the anaerobic Firmicutes (e.g., *Thermoanaerobacter* and *Thermoanaerobacterium*), protrusions of cell wall components have been observed to contain extracellular starch hydrolyzing enzymes (Antranikian et al., 1987).

SPORULATION (FIG. 2) One of the most characteristic properties of subgroups within the low G + C Gram-positive phylum is the formation of endospores. Some members of the high G + C Gram-positive group, for example those in the class Actinobacteria, form conidiospores, which differ sharply from endospores both in structure and formation. However, other genera of the Firmicutes, such as *Corynebacteria*, *Bifidobacterium*, *Athrobacter*, *Gardnerella*, and related bacteria are asporogenic (i.e., form neither conidospores nor endospores).

The extent and conditions for endospore formation varies greatly among the genera, species, and even between clones of the same strain in different laboratories (e.g., as demonstrated for *Moorella thermoacetica*; Wiegel et al., 1991). The extent of sporulation ranges from nearly 100% sporulation at end of the exponential growth phase in the presence of utilizable substrates (as in *C. paradoxum* → Lachnospiraceae; Li et al., 1993) to less than 0.01% sporulation under various starvation and sporulation-favoring conditions (as in *Thermoanaerbacter brockii*; Cook et al., 1991). However, although many species and strains among the Firmicutes do not exhibit spore formation under any of the standard sporulation conditions (e.g., stationary phase, starving conditions, unfavorable growth parameters, and growth on chopped meat agar), most possess most (if not all) of the sporulation-specific genes (Brill and Wiegel, 1997; Stragier, 2001; R. Onyenwoke and J. Wiegel, unpublished data). Since more than 75 gene products are
Fig. 2. Phase-contrast photomicrographs of some representatives of the genus *Clostridium*. Bar = 10 μm. (a) *C. butyricum* DSM 552; yeast extract-peptone agar; large, straight or slightly curved rods with round ends; sporangial cells slightly distended; oval, subterminal spores. (b) *C. thermocellum* DSM 1313; cellobiose medium; showing elongated sporulating cells with oval terminal spores. (c) *C. coccoides* DSM 935; CMC medium; coccobacilli to rod-shaped cells forming pairs and chains; round subterminal spores. (d) *C. oroticum* DSM 1287; CMC agar; rods occurring in long, tangled chains; enlarged sporangial cells with oval terminal-to-subterminal spores. (e) *C. indolis* DSM755; CMC agar; with round terminal-to-subterminal spores. (f) *C. cocleatum* DSM 1551; CMC agar; showing preponderance of semicircular-to-circular cell forms; oval spores are subterminal to terminal. (g) *C. bifermentans* DSM631; CMC agar; central-to-subterminal oval spores not distending cells. (h) *C. sporogenes* DSM 767; peptone-yeast extract-glucose medium; oval subterminal spores swelling the cells slightly. (i) *C. acetobutylicum* DSM 792; milk agar; rods of varying length; sporeforming cells cigar-shaped; spores oval to cylindrical, subterminal. (j) *C. ramosum* DSM 1402; CMC agar; showing tendency to Y- and V-shaped cells. (k) *C. cadaveris* DSM 1284; CMC agar; rods with oval terminal spores. (l) *C. tetanomorphum* DSM 665; CMC agar; large, straight to slightly curved rods; nearly round terminal spores. (From The Genus Clostridium—Nonmedical in the second edition.)
Fig. 2. *Continued*

sequentially required for sporulation, it is obvi-
ous that a mutation rendering one of the
required gene products nonfunctional leads
to naturally occurring sporulation-deficient
mutants and strains. This is especially true for
bacteria that grow like thermophiles in geother-
mally heated environments but under similar
continuous culture conditions. The isolation of
strains that lack observable sporulation is com-
mon among, e.g., butanol- and acetone-forming
C. acetobutylicum (Meinecke et al., 1984). The
reversion of sporulation-negative mutants (e.g.,

of *Bacillus pumilis*) to sporulating phenotypes
via bacteriophage treatment has been demon-
strated (Bramucci et al., 1977). Consequently,
species and strains that contain sporulation
genes but do not exhibit heat-resistant spore for-
mation are usually now termed "asporogenic" in
contrast to nonsporulating species that do not
possess most of the sporulation specific genes
(Brill and Wiegel, 1997; Byer et al., 2000). How-
ever, among the Firmicutes are genera assigned
to this branch on the basis of 16 rRNA gene
sequence analysis (see above), for which no

spore formation has been observed. Yet based on *B. subtilis* genome analysis and genome sequence comparison, some sporulation specific genes have been found (in Gram-type negative *Megasphaera elsdenii* or the Gram-type positive *Streptococcus*, *Staphylococcus*, *Listeria* and *Enterococcus*). The previous (Hippe et al., 1992) requirement of spore formation for the genus *Clostridium* sensu stricto or related genera is thus no longer valid. Another example is that absence or presence of spores cannot be used to differentiate between *Tissierella praeacuta* and *C. hastiforme* (Peptostreptoccocaeae) because *Tissierella* contains specific sporulation genes (R. Onyenwoke et al., unpublished results). Thus, the *T. praeacuta* type strain is regarded now as asporogenic with *C. hastiforme* as a sporulating strain.

The test for spores involves use of phase contrast light microscopy and heat resistance. To induce sporulation many *Clostridium* and related species and genera are grown on agar, especially chopped meat agar, or with poorly utilized sugars, which apparently does not lead to extremely heat resistant spores. Under the light microscope with phase contrast, forespores are black, whereas mature spores appear as bright refractile objects either still inside the more dark intact cytoplasm or less dark mother spore, or appear as spores released into the medium that may be associated with cell debris or cell material. Released spores (e.g., of *C. paradoxum*) can be clumped together in a gelatinous matrix (like frog eggs). The heat resistance test determines culture viability after a heat treatment at 80°C (mesophiles) to 100°C (thermophiles) for 10–20 min. Whereas most spores of mesophiles have a D-10 (exponential killing) time of less than a min at 121°C, spores of thermophiles (e.g., *Moorella thermacetica* strains) can have a D-10 time of up to 2 h (or above 1 h for *Thermoanaerobacterium thermosaccharolyticum*) at 121°C. The thermostability and drying resistance of spores can vary drastically with growth conditions (e.g., heterotrophic versus autotrophic) or temperature during sporulation (Byrer et al., 2000). So far, for *Clostridium* sensu stricto species, such high thermoresistance (especially of spores of pathogenic species) has not been observed, although note that for several species this feature has not been extensively tested.

Most of the species form only one spore either round or oval which is terminally, subterminally or centrally located in the mother cell, either without distending the mother cell (frequently seen for spores of *Bacillus* species with central locations but also seen in e.g., *C. bifermentans* and the type species of the genus *Clostridium*, *C. butyricum*, exhibiting central to subterminal oval

spores) or causing swelling of the mother cell (as seen, e.g., in *C. clostridioforme*, *C. chauvoei* and *C. sordellii*, which have central oval spores). In clostridial species (more rare in *Bacillus* species), round to slightly oval spores are frequently terminally located and distend the cells up to two times the width of exponentially growing vegetative cells and thus are often referred to as the "drumstick sporulation type." In several of these species, sporulation is accompanied by the formation of cells that are 2–10 times the length of a vegetative cell and either slightly less or much less than half the vegetative cell diameter (e.g., *C. hastiforme*, *C. kluyveri*, *C. lituseburense* and *C. sartogoforme*). The elongation occurs usually at the onset of the sporulation before forespores are visible (e.g., as in *C. thermocellum*). However, note that there is no real relation between specific sporulation type and specific group or genus (e.g., *Clostridium* = drumstick type versus *Bacillus* = central or subterminal type without a swollen sporangium, etc.) as has been depicted frequently in textbooks.

A few species among the Clostridiaceae produce two or more endospores. Examples include the bisporic *C. disporicum*, *C. oceanicum*, *C. lentocellum* and the polysporic *Anaerobacter polyendosporus*, which is closely related to *C. intestinale* (Murray et al., 1987; Siunov et al., 1999). One of the most interesting sporeformers is "*Metabacterium polyspora*," a symbiont of guinea pig gastrointestinal tract and the various fish symbionts "*Epulopiscium*" sp. (→ Lachnospiraceae). "*Metabacterium*" besides exhibiting symmetric cell division propagates mainly through forming several endospores by asymmetric division at both poles, which normally would only lead to two subterminal spores. However, the engulfed cell (forespore) of "*Metabacterium*" starts to divide by symmetric division leading to 2–9 spores per cell (see Angert and Losick [1998] and literature cited therein). Here sporulation is apparently converted from just being a dormancy and survival mechanism for overcoming temporary adverse environmental conditions to an unusual way of propagation, well-suited to the lifecycle of this intestinal symbiont. It is suggested that this could be the intermediate form between clostridial or bacillus-type sporulation and the viviparous formation of multiple offspring by internal reproduction in "*Epulopiscium*" (→ Lachnospiraceae; Collins et al. [1994] cluster XIVb) and related members of the order Clostridiales. So far, such features have not been observed within the Clostridiaceae. Since the intestinal flora of most insects (and other invertebrates) and of vertebrates are not known in detail, the existence of more bacteria belonging to the Firmicutes branch and even to the family Clostridiaceae, with this or similar, pres-

ently unusual, sporulation behavior can be expected (Angert and Losick, 1998).

PIGMENTS Unlike many aerobic and airborne bacteria, most cells of this group as well as most anaerobes do not contain bright pigments such as carotinoid derivatives. Surface colonies can be translucent to dull white and buff-colored to dark, dull or shiny gray. Cell pastes are frequently greenish gray or grayish black because of metal sulfide formation, although when grown under specific conditions can be brown to yellow brown because significant amounts of electron carriers such as ferredoxins and flavins are present. One unusual case is *C. puniceum*, belonging to *Clostridium* sensu stricto, which is pink when grown on potato-infusion agar but whitish when grown on blood or complex media (Lund et al., 1981).

Physiology

DIVERSITY The physiology and metabolism of members of the Clostridiaceae varies greatly and utilizes many different metabolic principles. The Clostridiaceae includes psychrophilic to thermophilic species (no hyperthermophiles have been reported within the Firmicutes), moderate halophiles, moderately acidotolerant species (up to pH 4.2), and alkaliphiles (pH$^{25C}_{opt}$ at or above pH 9). With respect to carbon source utilization, species include chemolithoautotrophs and various organoheterotrophs. The latter vary widely and include 1) saccharolytic species (which are able to use many or a few monocarbohydrates and one or more polymers such as starch, chitin, xylans and cellulose [but not lignin; lignin degradation under anaerobic conditions has not been demonstrated and is presently regarded as unlikely because lignin depolymerization proceeds via a radical mechanism]); 2) proteolytic and peptidolytic species and pairs of amino acid utilizers; 3) lipolytic and purinolytic species; 4) organic acid utilizers; and 5) C-1 compound utilizers (heterotrophic methylotrophs and chemolithoautotrophic C-1-utilizers).

Although most syntrophic Firmicutes species are now placed in the separate family Syntrophomonadaceae (Clostridiales), there is still one syntrophic *Clostridium* species, *C. ultunense*.

PHYSIOCHEMICAL BOUNDARIES FOR GROWTH *Anaerobic Metabolism and Oxygen Sensitivity* Generally clostridial metabolism is synonymous with obligately anaerobic metabolism, i.e., growth is not based on ATP formation using electron transport chain phosphorylation with O_2 as terminal electron acceptor (Gottschalk, 1986). None of the described *Clostridium* sensu stricto species (unlike *Desulfovibrio*; Escheman et al., 1999) has been shown capable of making ATP using O_2 as an electron acceptor. But even this characteristic, viewed in the past as the most fundamental one for the definition of clostridia and members of the Clostridiaceae, might not be true anymore. So far, no member of the family Clostridiaceae is truly facultative or obligately aerobic, using the above definition. But 16S rRNA gene sequence based phylogeny places the *Thermaerobacter* species (which are obligately aerobic thermophilic and sporeforming [except for the type species]) into cluster VIII of the Syntrophomonadaceae, despite the high G + C mol% of 72.5 for the type species (Takai et al., 1999; Nunoura et al., 2002; Spanovello et al., 2002).

Although they cannot use O_2 as terminal electron acceptor, many members of the Clostridiaceae can tolerate O_2, especially under nongrowth conditions, i.e., in the absence of utilizable substrates and energy sources. Many clostridial species stop growing when exposed to O_2 but resume growth under reinstated anoxic conditions (e.g., *C. butyricum*, *C. acetobutylicum* and *C. intestinale* [*Clostridium* sensu stricto], *C. aerotolerans* → Lachnospiraceae [O'Brien and Morris, 1971]; *C. paradoxum* → Peptostreptococcaceae, J. Wiegel, unpublished data). The oxygen concentration tolerated depends on the genus and species. Some species can grow under microaerophilic conditions, such as *C. haemolyticum* (*Clostridium* sensu stricto), which grows below a pO$_2$ of 0.5% (v/v), and *C. novyi* type A, which grows in the presence of up to 3% O_2. On the other hand, *C. novyi* type B (*Clostridium* sensu stricto) is killed when exposed to oxygen for a few min. When grown in nonagitated liquid cultures exposed to air, some species (e.g., *C. aerotolerans* → Lachnospiraceae; Van Gylswyk and Van Toorn, 1987) can reduce the redox potential of their medium below –120 mV (using resazurin as indicator). Cytochromes, menaquinones, catalase and superoxide dismutase are present at various levels. However, presently it is not known how strong the correlation is between the concentrations of the electron acceptors and enzymes and the O_2-tolerance of a specific strain. In many species the concentrations are below detection limits. In others they are at relatively high concentrations and can vary more than 60-fold depending on growth and stress conditions (McCord et al., 1971; Gottwald et al., 1975; Ashley and Shoesmith, 1977; Gregory et al., 1978; Cardenas, 1989) The oxygen sensitivity can be for various reasons, including 1) the usual damage of sensitive cell components by peroxides and radicals formed by interaction of media components and enzymatic reactions with O_2 and 2) specific effects such as the inhibition of the reduced nicotinamide adenine

dinucleotide (NADH)-oxidase causing a severe shortage of NADH (Uesugi and Yajima, 1978). In *C. aminovalericum*, a highly active NADH-oxidase with a K_m of ca. 62 μM O_2 is responsible for keeping the liquid media practically anoxic, thus this bacterium can grow in the presence of 3% O_2 (Kawasaki et al., 2004).

Temperature Most of the presently known members of the Clostridiaceae are mesophiles growing well in the range from around 10°C to slightly above 40°C. Two closely related moderate thermophiles, *C. palmarium* and *C. thermobutyricum*, with maximal growth temperatures below 65°C belong to the *Clostridium* sensu stricto. Most (extreme) thermophiles have been moved to different families (e.g., the well-studied *C. thermohydrosulfuricum* and *C. thermosaccharolyticum*, now species of the Thermobacteriaceae, *Thermoanaerobacter* and *Thermoanaerobacterium*, respectively). Several other thermophiles and extreme thermophiles (T_{max} >70°C to <80°C) still belong to the Clostridiaceae and are grouped together in the genus *Caloramator* (type species is the former *C. fervidus*) with species having the highest T_{max} values of around 75°C among the Clostridiaceae, closely related *Thermobrachium celer* and *Thermohalobacter berrensis*.

On the other end of the temperature spectrum are quite a few psychrotolerant and psychrophilic (T_{opt} below 15°C) Clostridiaceae species, including *C. arcticum*, *C. vincetii*, *C. algidicarnis* and *C. algidixylanolyticum*). Several psychrophilic and tolerant species were isolated recently from vacuum-packed meat (e.g., *C. estertheticum*, *C. frididicarnis*, *C. gasigenes* and *C. laramiensse*). One can assume that in the near future more psychrotolerant and psychrophilic clostridial species will be isolated owing to the renewed interest in low temperature-active enzymes for biotechnology (e.g., Cato et al., 1986; Broda et al., 2000).

pH Many clostridial species are neutrophiles although they can lower the pH to below 4.8 after 4–5 days of incubation in complex media. A few species such as the *Clostridium* sensu stricto species *C. acidisoli* and *C. akagii* (along with *C. pasteurianum* its closest relative; Kühner et al., 2000) are regarded as acid tolerant and able to grow atpH 3.6–7.0 with no distinct pH optimum, and at pH 4.0–9.0 with an optimum around 6.5 (Matthies et al., 2001). These isolates (with doubling times as short as 3.5 h at pH 4.0) are from acid forest soil. Most species cannot initiate growth at such low pH values and some species cannot grow below pH 6.2. However, cells may continue to metabolize and lower the pH further while their extracellular enzymes

continue to function (e.g., the cellulase complex of *Clostridium thermocellum* continues to degrade cellulose in mixed cultures down to pH 4.0). Some strains show only a slight or no acidification, and pH values in the cultures stay above pH 6.2 such as cultures of solvent-producing glycolytics or proteolytic, peptidolytic, and ammonium-producing strains growing in rich media (e.g., *C. sticklandii* and *C. aminophilum*). In butanol-producing species, a pH below 5.0 caused by the formation of butyric and other acids will trigger these bacteria (i.e., *C. acetobutylicum* and *C. beijerinckii*) to switch from acid production to the formation of pH-neutral compounds such as butanol and acetone, or butanol and ethanol, and even re-utilize the produced acids.

The inability to grow at low pH is used for excluding clostridia from fermentation processes to prevent production of, e.g., butyric acid during the lactic acid fermentation of silage or sauerkraut. Clostridial products such as sulfide or butyric acid would spoil the taste and smell, thus farmers acidify silage or cabbage by adding acetic acid or even mineral acids at the start of the fermentation. On the alkaline side, several clostridia can grow at pH values above 8.0, and even well above 8.5 (e.g., *C. histolyticum*) although their optimum is at neutral pH values (alkalitolerant species). True alkaliphilic species are the thermophilic *C. paradoxum* and *C. thermoalkaliphilum* ($\rightarrow$ Peptostreptococcaceae) with pH$^{25C\ optima}$ around pH 10. Souza (1974) reported on the isolation of alkaliphilic (growth up to pH 11.2) spore-forming anaerobes, but to date no species have been validly published. *Natronincola* (family Clostridiaceae; Zhilina et al., 1998) stands out among the true alkaliphiles, since it is also a moderately halophilic mesophile able to grow at pH values up to 10.5 with an optimum around 9.5.

Growth Rates Typically the shortest observed doubling times under optimal growth conditions for saccharolytic growth on monosaccharides is between 30 min and 3 h but can be as short as 10 min (e.g., in *Thermobrachium celer*, the fastest growing member of the Clostridiaceae; Engle et al., 1996). When growing on substrates such as crystalline cellulose (*C. thermocellum*; Freier et al., 1988) or chemolithoautotrophically, the shortest observed doubling times are about 5–8 h.

METABOLIC DIVERSITY The clostridia harbor quite a lot of physiological specialists, although the reassignment of many former *Clostridium* species has somewhat narrowed the spectrum. Many clostridial and related species require yeast extract or similarly complex media compo-

nents for optimal growth. The family Clostridiaceae includes species with broad substrate spectra but also species with narrow substrates. Some chemolithoautotrophic species (e.g., the iron(III)-reducing *Clostridium* species closely related [above 99% similarity at the 16S rRNA gene sequence level] to *C. thermobutyricum*; Wiegel et al., 2003) generate their ATP only via electron transport phosphorylation. With respect to fermentation products, family Clostridiaceae members include pH-neutral solvent producers, mixed acid and alcohol producers, and homoacidogenic fermenters.

Many of the *Clostridium* sensu stricto species exhibit mixed acid and alcohol fermentations, meaning they also form, besides the "genus-specific" product butyric acid, varying concentrations of acetic acid, lactic acid and/or ethanol, propanol or butanol. Similar to many other clostridial species, species which produce butyrate while growing on sugars use the Emden-Meyerhof-Parnass (glycolysis) pathway to convert sugars to pyruvate and then use pyruvate-ferredoxin oxidoreductase, acetyl CoA acetyltransferase, and some pathway-specific enzymes (for pathways, see Gottschalk [1986], White [1995], and Lengler et al. [1999]). The amount of butyrate produced depends strongly on the growth conditions. The *Clostridium* sensu stricto harbors the less-studied mesophile *Clostridium ljungdahlii*, which exhibits homoacetogenic fermentation that involves use of the Ljungdahl-Wood pathway and the characteristic enzyme CO-dehydrogenase/acetyl-CoA synthase found as well in the well-studied thermophile (now identified as *Moorella* species in the Thermoanaerobacteriaceae), which also exhibits homoacetogenic fermentation (Collins et al., 1994). *Clostridium formicoaceticum*, physiologically a very similar mesophile, belongs to cluster XI (Collins et al., 1994). The alkaliphilic, moderate halophilic *Natrononicola histidinovorans* uses the Ljungdahl-Wood pathway (acetyl-CoA pathway), but instead of using sugars as substrates, it oxidizes only histidine, glutamate and pyruvate (Zhilina et al., 1998). Despite its fermentative metabolism, *N. histidinovorans* proved to be obligately dependent on the activity of ion pumps (Pusheva et al., 1999). Lactate is a frequently observed fermentation product, especially with the saccharolytic species. Although several clostridia are inhibited by lactate concentrations far below 40 mM, some species can produce high concentrations (more than 150 mM) of lactate as the main fermentation product (*C. stercorarium* subsp. *thermolacticum*). Lactate, however, can serve as substrate for other fermentation specialists including *C. homopropionicum* (*Clostridium* sensu stricto), *C. propionicum*, *C. neopropionicum* and *C. lactati-*

fermentans (all cluster XIVb; Collins et al., 1994) exhibiting fermentation of lactate to propionic acid and acetate using the acrylate pathway. They can also utilize other substrates such as ethanol and CO (in the case of *C. neoproprionicum*) and amino acids via pyruvate disproportionation (in the case of *C. propionicum*). This acrylate pathway is also used by other members in different families of the Clostridiales, e.g., *Megasphaera* (Seeliger et al., 2002). The energetically more efficient succinate pathway to form propionate used by the propionibacteria is not used by members of the Clostridiaceae (Dorner and Schink, 1990; Tholozan et al., 1995; Van der Wielen et al., 2002).

Clostridium sensu stricto species (e.g., *C. beijerinckia* and *C. acetobutylicum*) produce another well-known clostridial fermentation product butanol together with either ethanol or acetone. This fermentation uses initially the same pathway as the butyric acid fermentation and reduces the acid moiety to the pH neutral compound butanol (using the acid as an additional electron acceptor). Many *C. butyricum* strains produce as a main alcohol propanediol when growing on glycerol. No longer among the Clostridiaceae do the species exhibit a yeast-like ethanol fermentation. These species have now been moved to Thermoanaerobacteriaceae. However, some *Clostridium* sensu stricto species can produce relatively high concentrations of ethanol from peptides and proteins, a property that can lead to elevated post-mortem blood ethanol concentrations (Wiegel, 1980).

A special physiological case is represented by *C. kluyveri* which using a special pathway involving acyl~CoA transferases is able to use ethanol and reduce it to caproate and butyrate with acetate as the oxidized acid product. This species can also use crotonate as substrate for growth, producing butyrate, 2 acetates and 1 ATP. This latter pathway is also used by obligate syntrophic clostridia species belonging now to the family Syntrophomonadaceae.

An environmentally and physiologically interesting group is the purinolytic clostridia (e.g., *C. acidurici* and *C. purinolyticum*), which use purines, uric acid derivatives, and pyrimidines. They use special pathways with their interesting selenocysteine-containing enzymes (e.g., purine hydroxylase and xanthine dehydrogenase; Dürre et al., 1981; Self, 2002) to anaerobically degrade nucleic acids and their hydrolysis products. Somewhat related are other heterocyclic compound degraders that degrade nicotinic acid and pyridine derivatives (Kaiser et al., 1996; Andreesen, 2003). Many of these also can utilize amino acids. A great variety of degradation pathways for amino acid utilization exist among the Clostridiales and even among the Clostridiaceae

depending on the amino acid and clostridial species. These pathways frequently include the hydroxyacid pathway, the methylaspartate pathway for rearranging the carbon skeleton, and B12-dependent enzyme reactions. For an overview of the different pathways, which is outside of the scope of this chapter, see The Anaerobic Way of Life in volume 2. Among the special amino acid-utilizing clostridial species worth mentioning here are *C. sticklandii* (→ Peptostreptocaccaceae) and related species. These perform the Stickland reaction with amino acid pairs: one is oxidized to an acid that is one carbon shorter, and the other is reduced to the corresponding fatty acid. Environmentally important species also include clostridia (e.g., *C. methoxybenzovorans* (→ Lachnospiraceae), and the *Clostridium* sensu stricto species *C. pfennigii* (forming butyrate) and *C. scatologenes*) that can use methoxy aromatic compounds. This reaction is regarded as important in the anaerobic degradation and mineralization of lignin and because of its breakdown products including vanillic acid.

Genetics

Knowledge of the genetics of clostridia and how to manipulate DNA in several clostridial species has greatly expanded in recent years. Most of the work in the area has focused either on the pathogenic clostridia or the (potentially) important solvent-producing clostridia. However, the basic information should apply to many other species in the Clostridiaceae.

Fortunately, much of the knowledge on the genetics of clostridia has been summarized in a number of review articles over the past 15–20 years. A review by Rogers (1986) summarized the literature on mutation of clostridia, plasmids in clostridia, genetic transfer, and cloning of genes in *E. coli*. Ultraviolet (UV) light, *N*-methyl-*N*'-nitro-*N*-nitrosoguanidine, and the combination of UV and especially ethylmethanesulfonate has been used to obtain clostridial mutants. Minimal defined media for *C. acetobutylicum* were identified (e.g., Long et al., 1983), making the isolation of mutants with auxotrophic markers feasible. Plasmids, primarily cryptic, were isolated from eight clostridia, primarily pathogenic species or solvent-producing species. Clostridial bacteriophages are known, and the literature on these has been reviewed (Mahony, 1979). Conjugation in *C. perfringens* has been demonstrated (Abraham et al., 1985), as has transformation using protoplasts.

By the time a review by Young et al. (1989) was published, the more promising technique of electroporation had been used as a tool for transformation in clostridia (Allen and Blaschek,

1988). Transposons, which can be used for mutagenesis or cloning, were available for clostridial systems (Wust and Hardegger, 1983). A number of clostridial genes had been cloned into *E. coli* (Youngleson et al., 1988). This is a useful research tool, but direct genetic manipulations in a clostridial species itself will be required for improving applications in solvent production.

Several chapters covering bacteriophages, plasmids, transposon mutagenesis, and transformation in pathogenic clostridia are presented in a book edited by Rood et al. (1997). It contains a chapter on the phylogenetic heterogeneity, or complexity, of the clostridia (Stackebrandt and Rainey, 1997), along with a good review of sporulation in clostridia (Labbe and Shih, 1997).

A chapter on the genetics of clostridia by Mauchline et al. (2000) appeared in the second edition of the *Manual of Industrial Microbiology and Biotechnology* (Demain and Davies, 2000). The genetics of solvent-producing clostridia was the focus of this chapter. Procedures reviewed included transformation by electroporation, use of broad-host-range conjugative plasmids for genetic manipulation, and use of conjugative transposons for genetic manipulations.

A recent review by Tummala et al. (2001) on genetic tools for clostridia also focused on the solvent-producing clostridia. Two other procedures for manipulating these clostridia were described, including development of gene expression reporter systems (Tummala et al., 1999) and the use of antisense RNA for metabolic engineering of clostridia (Desai and Papoutsakis, 1999).

Mai and Wiegel published an overview of the genetics of thermophiles including thermophilic Firmicutes (Mai and Wiegel, 1999; Mai and Wiegel, 2000), which should also apply to the thermophiles of the clostridia sensu stricto. Spheroplasts (autoplasts) from *C. thermobutyricum* have been regenerated (J. Wiegel, unpublished data) by the described methods used for other Firmicutes.

An important, and still not fully exploited, advance in the genetics of clostridia is complete genome sequencing. Genome sequences are now available for *C. perfringens*, *C. acetobutylicum* and *C. tetani* (Bruggemann et al., 2003). An interesting finding was the presence of 35 genes involved in sodium ion bioenergetics in *C. tetani*, in addition to a number of virulence genes such as toxin-, collagenase-, and adhesion protein genes. There have been a lot of advances in the genetics of clostridia in the past decade and, given continued interest in their capabilities as pathogens or alcohol producers, these advances should continue.

Industrial Applications

A description of the industrial application and medical importance of the species belonging to the Clostridiaceae (even for the species belonging to *Clostridium* sensu stricto) would go far beyond the scope of this chapter. The reader is referred to specialized reviews and book chapters (Smith and Williams 1984; Ljungdahl et al. 1989a; Ljungdahl et al. 1989b; Rood et al., 1997; Sussman 2001; Dürre, 2004; de la Maza et al., 2004).

Best known among industrial applications from the past is probably the acetone-butanol fermentation using *C. acetobutylicum* and various related strains. In the future, the application of clostridial and related strains will probably shift more to the use of recombinant enzymes, or products from them, expressed in different industrial expression vectors. An excellent historical review on the diversity of isolates and given names has been published by Jones and Keis (1995) and Johnson and Chen (1995) and provides an example of how pre-16S rRNA sequence analysis taxonomy and industrial interest led to confusion in the describing of species of clostridia.

CHAPTER 1.2.21

Neurotoxigenic Clostridia

CESARE MONTECUCCO, ORNELLA ROSSETTO AND MICHEL R. POPOFF

Introduction

Certain bacterial species of the genus *Clostridium* are characterized by their ability to produce extremely potent neurotoxins: tetanus neurotoxin (TeNT) and botulinum neurotoxin (BoNT). TeNT inhibits neurotransmitter release of synapses of the central nervous system (CNS) causing the spastic paralysis of tetanus; BoNT inhibits the release of acetylcholine at peripheral cholinergic nerve terminals causing the flaccid paralysis of botulism. To date, one TeNT and seven (A–G) serologically distinct BoNTs are known (Schiavo et al., 2000).

Clostridium Tetani

Morphological and Cultural Characteristics

Tetanus neurotoxin (TeNT) is produced by a uniform group of bacteria belonging to the *Clostridium tetani* species. These bacteria are usually 0.3–0.6 μm in width and may vary considerably in length between 3 and 12 μm. They are Gram positive in young cultures, but they lose the Gram coloration upon prolonged incubations. *Clostridium tetani* is usually highly motile by peritrichous flagella, a property responsible for the swarming growth on agar medium, though some strains have no flagella. *Clostridium tetani* sporulates by forming translucid terminal enlargements, which give the typical drumstick appearance (*Clostridium* in Latin). The sporulation rate varies with the nature of the culture medium, strains, pH and temperature; sporulation does not take place above 41°C and at pH < 6 (Bytchenko, 1981). Spores are inactivated within one h at 100°C.

Germination of *C. tetani* spores occurs both under anaerobic and aerobic conditions, but the outgrowth of *C. tetani* is strictly dependent upon a low oxidation-reduction potential (Smith and Williams, 1984). *Clostridium tetani* is strictly anaerobic, and motile strains swarm over the entire surface of the agar leading to a transparent film. Discrete colonies (2–5 mm) can be obtained with media containing 3–4% agar. On blood agar, colonies are slightly raised, semitranslucent, gray, with an irregular margin and surrounded by a narrow zone of hemolysis. *Clostridium tetani* grows fairly well on the usual media containing peptones or tissue extracts.

Most of the usual biochemical tests used for *Clostridium* identification are negative, as no carbohydrates are acidified, and there is no proteolysis, and no lipase or lecithinase production. Gelatin is liquefied slowly (2–7 days) with production of H_2S and indole (Smith and Williams, 1984).

Genetic Characteristics

The *Clostridium* genus encompasses more than 100 species that display a wide range of phenotypes and genotypes (Hippe et al., 1992). *Clostridium tetani* has been classified in group II on the basis of 23S rRNA homology (Johnson and Francis, 1975).

The complete genome sequence of a toxigenic *C. tetani* strain consists of a 2,799,250-bp chromosome containing 2372 putative genes and a 74,082-bp plasmid, containing 61 genes (Brüggemann et al., 2003). *Clostridium tetani* possesses many genes for peptidases and for amino acid and lipid degradation, whereas genes for sugar utilization are lacking. It contains numerous transport-related genes; in particular, 35 genes for sodium ion-dependent systems indicate that Na^+ gradient is a major driving force in membrane transport. The TeNT encoding gene and seven putative regulatory genes are localized on the plasmid, whereas the tetanolysin (an hemolysin) gene and putative adhesin genes are located on the chromosome. Many genes encoding for putative adhesins have been identified: 2 fibronectin-binding proteins, 11 related surface-layer proteins, 19 homologues to a *Clostridium difficile* adhesin, and 2 proteins with multiple leucine-rich repeat domains similar to the *Listeria monocytogenes* internalin A (Brüggemann et al., 2003).

Clostridia Producing Botulinum Neurotoxins

BoNT-producing *Clostridia* display heterogeneous bacteriological characters and are divided

into several species and groups. The taxonomic position of the *C. botulinum* species was originally based on the production of a BoNT, and nontoxic variant strains, although genetically related to *C. botulinum*, were assigned to different species. Moreover, there are seven different serologically distinct BoNTs termed "A" to "G." *Clostridium botulinum* strains were divided into four physiological groups (Smith and Williams, 1984). Group IV includes *C. botulinum* G strains, which have been assigned to a different species termed "*C. argentinense*" (Suen et al., 1988).

BoNT can be produced by other *Clostridium* species such as *C. butyricum* and *C. baratii*, which have been implicated in human botulism. The toxinogenic property of the *Clostridium* strains remains an important characteristic, mainly in clinical aspects, but this single property is not sufficient to define a bacterial species. Moreover, toxigenicity is unstable, and it appears to be transferable to a wide variety of *Clostridium* species (Hatheway, 1990).

Morphological Aspects

BoNT-producing *Clostridium* are usually straight to slightly curved rods, 0.6–2 μm wide and 2–22 μm long. They are usually motile and have peritrichous flagella, except *C. baratii*, which is nonmotile. Spores are oval and swell one terminus of the cell. Type G strains sporulate poorly, and *C. butyricum* spores are central to subterminal and usually do not swell the cell (Cato et al., 1986).

These bacteria grow well in usual anaerobic liquid media with production of gas. Surface colonies can be grown on blood agar plates, incubated under anaerobic conditions; they can be circular (1–6 mm in diameter) or irregular, with a scalloped or lobate margin, translucent to semiopaque, and gray-white. A narrow zone of partial hemolysis surrounds colonies of BoNT-producing *Clostridium*, except colonies of *C. butyricum*, which is nonhemolytic.

Physiological Characters

Group I (*C. botulinum* A and proteolytic strains of types B and F) is characterized by proteolytic activity and by the nonacidification of carbohydrates. The optimal temperature of growth is 37°C. The thermoresistance of the spores is usually high (above 120°C; Smith and Williams, 1984).

Group II (*C. botulinum* E and glucidolytic strains of types B and F) acidifies many carbohydrates and produces mainly butyric and acetic acids from trypticase-yeast extract-glucose broth. They hydrolyze gelatin, but they are nonproteolytic (Cato et al., 1986). They have a lower

optimal temperature of growth (around 25–30°C), and they can grow and produce toxins at very low temperature. Spores are only moderately resistant to heat (not withstanding 10 min at 90°C; Smith, 1992).

Group III (*C. botulinum* C and D) is poorly proteolytic and is rather heterogeneous with respect to sugar fermentation and production of indole and hydrogen sulfide (Oguma et al., 1986). These bacteria grow at higher temperature than the other *C. botulinum* strains (30–37°C optimal range), with most strains growing well up to 45°C (Cato et al., 1986). Heat resistance of spores is intermediate.

Group IV (*C. argentinense*) is proteolytic, hydrolyzes gelatin, and does not ferment any of the usual carbohydrates. In contrast to the other strains of the *C. botulinum* groups, *C. argentinense* strains do not produce a lipase. The optimum temperature of growth is 30–37°C. Phenotypic differences have been observed between toxic and nontoxic strains by using cellular fatty analysis and multilocus enzyme electrophoresis (Ghanem et al., 1991).

Clostridium butyricum toxigenic strains are nonproteolytic, do not hydrolyze gelatin, and acidify strongly various carbohydrates, but they do not produce lipase or lecithinase (Smith, 1992). Toxigenic and nontoxigenic *C. baratii* strains display similar morphological and biochemical characteristics and are phenotypically related to *C. perfringens*. They produce a lecithinase but not a lipase. *Clostridium baratii* is readily differentiated from *C. perfringens* by its lack of hydrolysis of gelatin (Cato et al., 1986).

Genetic Characteristics

All the BoNT-producing *Clostridium* strains belong to the 23S rRNA homology group I (Johnson and Francis, 1975), which also includes *C. butyricum*. The genome sequence of *C. botulinum* A strain Hall is completed Sanger Microbes Project website (http://www.sanger.ac.uk/Projects/Microbes/). The chromosomal genome (3,888,916 bp) is larger than that of *C. tetani*. In addition to the botulinum locus, this strain contains two putative hemolysin genes on the chromosome and a small plasmid (16 kbp) containing a bacteriocin gene.

Genetics of Clostridial Neurotoxins

Neurotoxin Genes

The genes encoding the neurotoxins and associated nontoxic proteins (ANTP) have been cloned and sequenced in representative clostridial strains of each BoNT type (Popoff and

Eklund, 1995). The neurotoxin and ANTP genes are clustered (botulinum or tetanus neurotoxin locus). The organization of the botulinum locus is conserved in the 3′ part but differs slightly in the 5′ part in the different types of BoNT-producing *Clostridia*. The *bont* genes are preceded by the genes of the nontoxic nonhemagglutinin (NTNH) components. The *ntnh* and *bont* genes are transcribed in the same orientation (Fig. 1), whereas the hemagglutinin (HA) genes (*ha*33, *ha*17 and *ha*70) are transcribed in the opposite orientation. The *ha* genes are missing in the nonhemagglutinating toxinotypes A2, E and F. The *ha* genes of *C. botulinum* G only comprise *ha*17 and *ha*70. In toxinotypes A, E and F, a gene (*p47*) encoding a 47-kDa protein is immediately upstream of the *ntnh* gene, and both genes are transcribed in the same orientation. In addition, two genes (*orfX1* and *orfX2*), which are not related to *ha*, lie upstream of *p47*. A gene (*botR*, previously called "*orf*21" or "*orf*22") encoding a 21–22-kDa protein, which presents features of a regulatory protein, is present in different positions in different strains of *C. botulinum* (Fig. 1). In *C. tetani*, a gene (*tetR*) equivalent too *btR* is upstream of the *tetx* gene. No *antp*-like genes have been identified in *C. tetani* (Brüggemann et al., 2003).

Usually, one clostridial strain produces only one type of neurotoxin and the botulinum locus is present in a single copy on the genome; however, some rare strains synthesize two different BoNTs: BoNT/A-BoNT/B, BoNT/A-BoNT/F, and BoNT/B-BoNT/F (Lin and Johnson, 1995; Hutson et al., 1996; Henderson et al., 1997); the A-B strain contains two bont genes related to those of *C. botulinum* A and proteolytic *C. botulinum* B, respectively (Fujinaga et al., 1995). In such strains, the two neurotoxins are usually produced in different proportions (Henderson et al., 1997). Clostridial strains containing silent neurotoxin genes have been detected (Franciosa et al., 1994; Hutson et al., 1996; Jovita et al., 1998).

Genomic Localization and Transfer

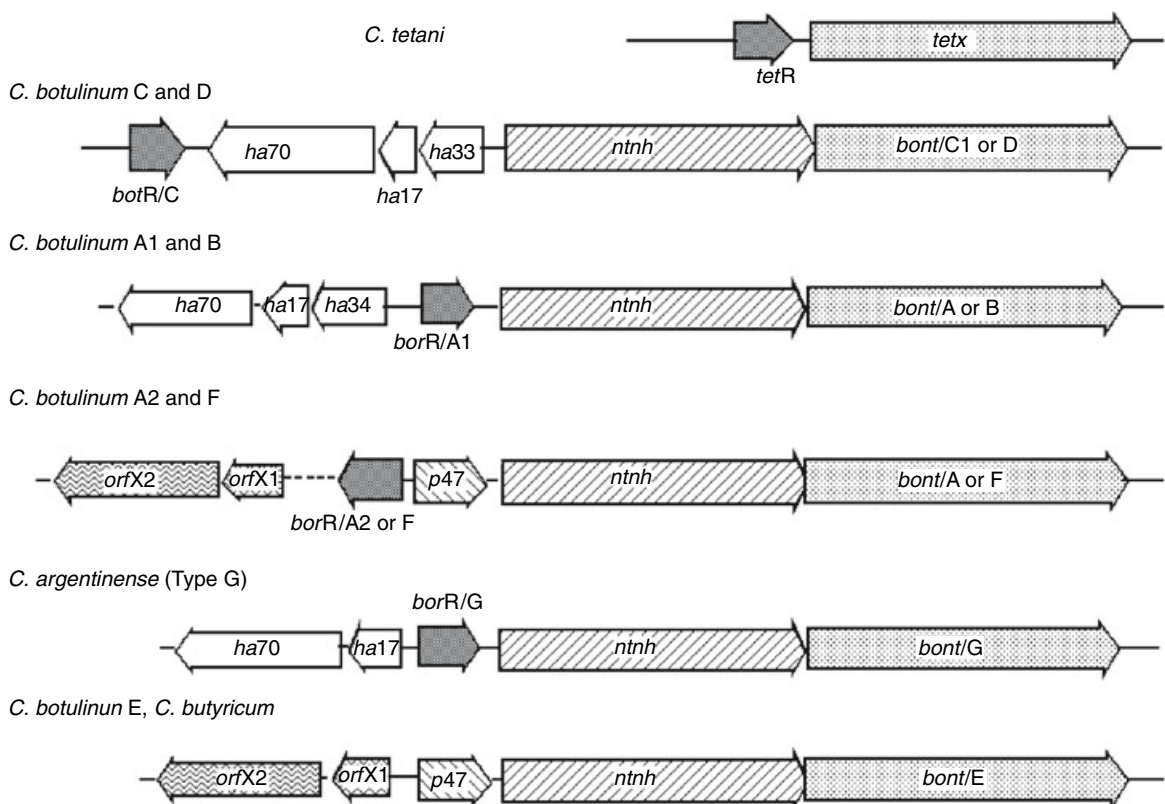
The genes encoding for the different types of BoNT are present on different genetic elements, including phages, plasmid or chromosomes depending on the species and strain of *Clostridia* (Minton, 1995). These genes are linked to genetically mobile elements allowing for a loss or acquisition of neurotoxigenicity. In *C. tetani* and *C. argentinense*, the neurotoxin gene is present within a large plasmid, and in *C. botulinum* A, B, E and F, the toxin genes


Fig. 1. Genetic organization of the botulinum and tetanus locus in *C. tetani* and in the different *C. botulinum* toxinotypes.

are located on the chromosome (Popoff and Eklund, 1995). *Bont/C* and *bont/D* are present within bacteriophages and their genes can be transferred in different *Clostridium* host strains determining their toxinotypes; indeed, transposable elements have been identified in *C. botulinum* C and D (Popoff and Eklund, 1995). A pseudolysogenic relationship corresponding to the presence of bacteriophages free within the bacterial cytoplasm exists between these phages and hosts. Thus, variants free of bacteriophages can be obtained with high frequency using curing reagents such as acridine orange and ultraviolet light. Under laboratory culture conditions, a proportion of the bacteria (depends on the strain and growth conditions [temperature and salinity]) is lysed and loses free bacteriophages that can reinfect them. Such lysogeny and reinfection cycles occur probably in the environment (soil and intestinal tract of birds and animals) and account for the isolation of nontoxigenic or low toxin producer variants (Eklund and Dowell, 1987).

In *C. botulinum* A and F, the involvement of bacteriophages in neurotoxin gene transfer has been suggested on the basis of the identification of a gene (*lyc*) in the vicinity of the *bont* genes. Since lytic enzymes participate in the bacteriophage life cycle, this could indicate that the botulinum locus is part of an integrated prophage. In *C. botulinum* A strain Hall, the *botulinum* locus is flanked by two insertion sequences in the 5′ part and by a transposase gene in the 3′ part. The *bont/E* gene has been transferred from a neurotoxigenic *C. butyricum* strain to a nontoxigenic *C. botulinum* E strain following a protocol resembling transduction with a defective phage (Zhou et al., 1993) suggesting that the reverse transfer may take place as well (Poulet et al., 1992).

The similarity among the different BoNTs and with TeNT, the fact that different *Clostridium* species can produce BoNT and that some strains contain combinations of *bont* genes (Franciosa et al., 1997; Henderson et al., 1997) strongly suggest that *bont* and *tetx* genes derive from a common ancestor and have been transferred between *Clostridium* strains.

Structure and Mode of Action of Clostridial Neurotoxins

The seven botulinum neurotoxins (BoNTs, types A–G) and the single tetanus neurotoxin (TeNT) are responsible for the clinical manifestations of botulism and tetanus, respectively. BoNTs bind to, enter peripheral cholinergic terminals, and cause a sustained block of acetylcholine release,

with ensuing flaccid paralysis and loss of function of autonomic glands. By contrast, TeNT reaches the CNS by retrograde axonal transport inside the axons of motor neurons and blocks neurotransmitter release at the inhibitory interneurons of the spinal cord, resulting in a spastic paralysis.

These neurotoxins are metalloproteases and exert their enzymatic action in the cell cytosol on selected proteins that form the core of the neuro-exocytosis machinery. As a result of such double specificity of binding (presynaptic membrane and substrate) and of their catalytic activity, these neurotoxins are the most potent toxins known, with a mouse 50% lethal dose (LD_{50}) between 0.1 ng and 1 ng of toxin per kg of body weight. Such extremely low values are expected to be even lower in the wild, where even a very small deficit in mobility may be sufficient to impair the survival of intoxicated animals. Different animal species show a large range of sensitivity to TeNT and to the different BoNTs. Humans and horses are even more sensitive to these neurotoxins than mice, whereas rats, birds, snakes and amphibians are rather resistant to TeNT, and turtles are insensitive (Payling-Wright, 1955; Gill, 1982).

Toxin Structure

The similar effect of the eight clostridial neurotoxins (CNTs) on nerve terminals is the result of a closely related protein structure. They are synthesized in the bacterial cytosol as a 150-kDa polypeptide chain without a leader sequence and are released in the culture medium only after bacterial autolysis. No protein is associated with TeNT, whereas the BoNTs are released in the form of multimeric complexes with a set of nontoxic proteins (Minton, 1995; Inoue et al., 1996). Some BoNT-associated proteins have hemagglutinating activity: HA of 17 kDa (HA17), HA of 34 kDa (HA34) and HA of 71 kDa (HA71). In addition, a large nontoxic, nonhemagglutinating protein of 139 kDa (NTNH) is always present, and it has been suggested that it nests the formation of the BoNT-NTNH complex, which may or may not progress to the formation of larger complexes. In fact, three forms of progenitor toxins have been characterized: extra-large size (LL sediments at 19S, approximately 900 kDa); large size (L sediments at 16S, 500 kDa), and medium size (M, sediments at 12S, 300 kDa). Complexed BoNTs are more stable than isolated BoNTs to proteolysis and denaturation induced by temperature, solvent removal, or acid pH, and to lyophilization (Sakaguchi, 1983; Chen et al., 1998). Toxins are adsorbed during their passage across the gastrointestinal tract and have been shown to transcytose across polarized epithelial mono-

layers (Maksymowych and Simpson, 1998; Simpson, 2000).

The single chain 150-kDa neurotoxins are inactive and are activated by specific proteolysis within a surface exposed loop subtended by a highly conserved disulfide bridge (Fig. 2). Several bacterial and tissue proteinases are able to generate the active di-chain neurotoxin. The heavy chain (H, 100 kDa) and the light chain (L, 50 kDa) remain associated via noncovalent interactions and via the conserved interchain S-S bond, whose integrity is essential for neurotoxicity (Schiavo et al., 1990; De Paiva et al., 1993).

The length of the polypeptide chains of CNTs varies from the 1251 amino acid residues of *C. butyricum* BoNT/E to the 1297 residues of BoNT/G and the 1315 residues of TeNT (Niemann, 1991). The exact length of the L and H chains depends on the site of proteolytic cleavage within the exposed loop. The H chains vary in size from the 829 amino acid residues of BoNT/E to the 857 residues of TeNT. The L chains range in size from the 419 amino acid residues of BoNT/E to the 449 residues of TeNT (Fig. 2), and its most conserved portions are the amino-terminal one hundred residues and the central region (residues 216–244; numbering of TeNT), containing the His-Glu-Xaa-Xaa-His binding motif of zinc-endopeptidases (where "Xaa" indicates any amino acid; Fig. 2).

The crystallographic structures of BoNT/A and BoNT/B and of the carboxy-terminal TeNT domain (Hc) reveal the presence of three distinct 50-kDa domains: a) an N-terminal domain endowed with zinc-endopeptidase activity (L chain), b) a membrane translocation domain (H_N) characterized by the presence of two 10 nm-long α-helices, which are reminiscent of elements present in colicins and in the influenza virus hemagglutinin, and c) a binding domain (H_C), composed of two subdomains, termed "H_C-N" and "H_C-C" (Umland et al., 1997; M. Knapp and B. Rupp, Protein Data Bank accession number 1A8D, 1998; Lacy et al., 1998; Swaminathan and Eswaramoorthy, 2000; Fig. 3).

This structural organization is functionally related to the four-step mechanism of neuron intoxication by CNTs, consisting of: 1) binding, 2) internalization, 3) membrane translocation, and 4) enzymatic target modification (Montecucco et al., 1994; Montecucco and Schiavo, 1995; Fig. 4). The L chain is responsible for the intracellular catalytic activity, the amino-terminal 50-kDa domain of the H chain (H_N) is implicated in membrane translocation, and the carboxy-terminal part (H_C) is mainly responsible for the neurospecific binding.

THE BINDING DOMAIN The H_C binding domain of these CNTs consists of two distinct subdo-mains, the N-terminal half (H_C-N) and the C-terminal half (H_C-C), with few protein-protein contacts between them. H_C-N is similar to some legume lectins, which are carbohydrate-binding proteins. The amino acid sequence of this subdomain is highly conserved among CNTs suggesting a very similar folding. The Hc-C subdomain contains a modified β-trefoil folding motif present in several proteins involved in recognition and binding functions such as IL-1, fibroblast growth factor, and the Kunitz-type trypsin inhibitors. Its sequence is poorly conserved among CNTs. It harbors one binding site for the oligosaccharide portion of polysialogangliosides in BoNT/A and /B, while the H_C-C of TeNT has two such sites (Rummel et al., 2003a; Rummel et al., 2003b).

THE TRANSLOCATION DOMAIN The H_N portions of BoNT/A and /B are very similar, and their sequences are highly homologous among the various CNTs. H_N has a cylindrical shape determined by the presence of a pair of unusually long and twisted 10-nm long α-helices, corresponding to segment 685–827 of BoNT/A (Lacy et al., 1998; Swaminathan and Eswaramoorthy, 2000; Fig. 3). At both ends of the pair, there is a shorter α-helix, which lies parallel to the main helices, and several strands packed along the two core helices. The overall structure of H_N resembles that of some viral proteins that undergo an acid-driven conformational change (Bullough et al., 1994; Weissenhorn et al., 1997).

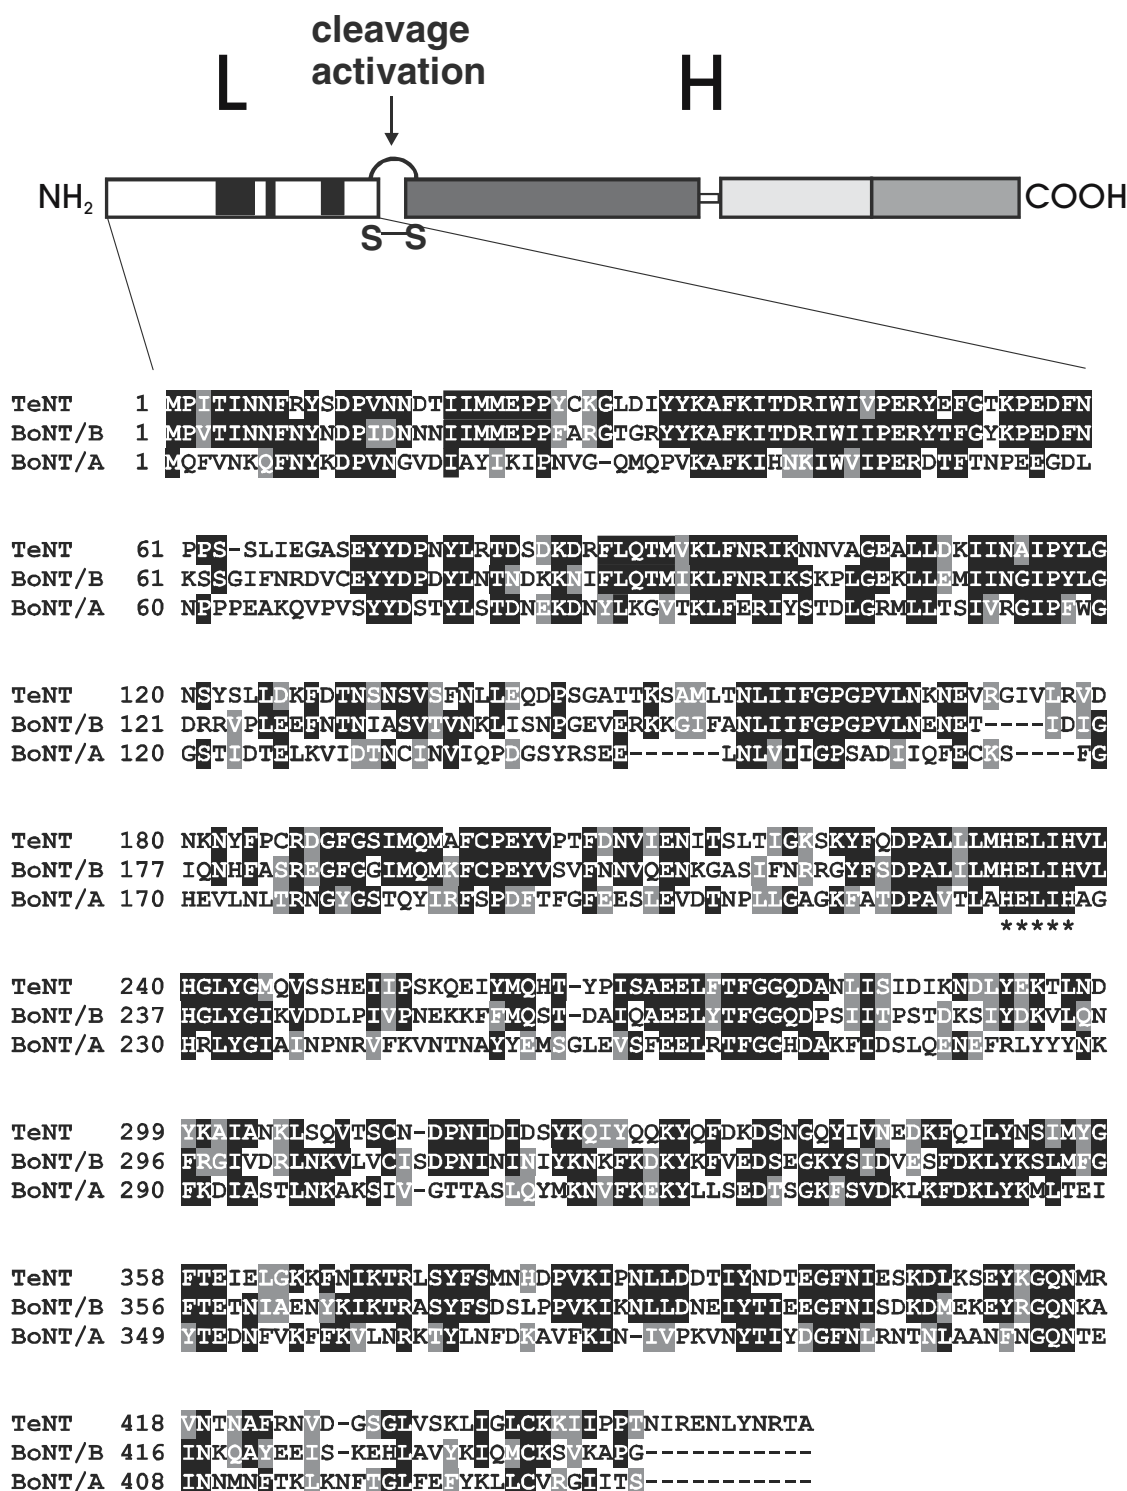
THE CATALYTIC DOMAIN The metalloprotease domain has little similarity with related enzymes of known structure, apart from the α-helix segment including the zinc-binding motif (Fig. 3). The active site zinc atom is coordinated by the imidazole rings of the two histidines of the motif, a water molecule bound to the glutamic acid of the motif and a glutamic acid, which is conserved among clostridial neurotoxins. The Glu residue of the motif is particularly important because it coordinates the water molecule directly implicated in the hydrolytic reaction of proteolysis. Its mutation leads to complete inactivation of these neurotoxins (Li et al., 2000). The active site is similar to that of thermolysin and identifies a primary sphere of residues essential to the catalytic function, which coincides with the zinc coordinating residues. In addition, a secondary layer of residues, less close to the zinc center (including Arg362 and Tyr365 [numbering of BoNT/A]), appears to be directly involved in catalysis by providing transition state stabilization (Rigoni et al., 2001; Rossetto et al., 2001a; Binz et al., 2002). The active site of BoNTs is long and deep and shielded by the H chain; it becomes accessible to the substrate upon reduction of the interchain


Fig. 2. Schematic structure of clostridial neurotoxins (CNTs) and amino acidic sequence of tetanus neurotoxin (TeNT), botulinum neurotoxin (BoNT)/B and BoNT/A L-chains. The neurotoxins are synthesized in the bacterial cytosol as inactive 150-kDa proteins and are activated by specific proteolysis within a surface exposed loop. These toxins are composed of a heavy chain (H, 100 kDa) and a light chain (L, 50 kDa), which remain associated via noncovalent interactions and via the conserved interchain S-S bond. The light chain is a zinc-endopeptidase acting in the neuron cytosol. The central region of the L chain (residues 216–244, numbering of TeNT) contains the His-Glu-Xaa-Xaa-His binding motif of zinc-endopeptidases (indicated by asterisks).

Fig. 3. Three-domain structure of clostridial neurotoxins. The crystallographic structure of botulinum neurotoxin (BoNT)/A highlights the three 50 kDa-domain structure, with the zinc atom (red ball) held in the center of the active site of the L chain (Lacy et al., 1998). The α-helix containing the HEXXH motif is shown in orange. The H_N domain is characterized by two 10 nm long pair of α-helices and is responsible for the membrane translocation of the L chain into the neuronal cytosol. The C-terminal H_c domain consists of two equally sized subdomains. The N-terminal one (H_{CN}) has two seven-stranded β-sheets similar to that of sugar binding proteins. The C-terminal one (H_{CC}) has a β-trefoil fold similar to that of the K^+ channel specific snake dendrotoxin. This part harbors the polysialoganglioside binding site of BoNT/A.
Fig. 4. Current view of tetanus neurotoxin (TeNT) and botulinum neurotoxins (BoNTs) entry at nerve terminals. BoNTs and TeNT bind to multiple receptors present within lipid microdomains of the presynaptic membrane of peripheral nerve terminals via the Hc domain. TeNT Hc is shown to interact with a glycosylphosphatidylinositol (GPI)-anchored protein (Thy-1) and to bind to two molecules of polysialogangliosides present within lipid microdomains in neurospecific binding that may be implicated in its internalization (see the inset). Binding is followed by internalization inside endocytic vesicles, whose lumen becomes acid following the activity of an ATPase proton pump. At low pH, BoNTs change conformation, insert into the lipid bilayer of the vesicle, and translocate the L chain into the cytosol. By contrast, TeNT is internalized and transported retroaxonally to the spinal cord (not shown) where it enters the inhibitory interneuron terminals as depicted here for the BoNTs at cholinergic peripheral terminals. Inside the cytosol, the L chain catalyzes the proteolysis of one of the three soluble *N*-ethylmaleimide sensitive factor-attachment protein receptor (SNARE) proteins. The capital letters indicate the serotype of the toxin acting on different targets.

disulfide bridge, and it appears to be capable of accommodating a 16-residue-long segment of the substrate.

Mode of Action of Clostridial Neurotoxins

NEUROSPECIFIC BINDING (STEP 1 OF FIG. 4) From the site of production or adsorption (intestine or wounds), BoNTs and TeNT diffuse in the body fluids. BoNTs bind with high affinity and specificity to the presynaptic membrane of skeletal and autonomic cholinergic nerve terminals; in addition, TeNT also binds to sensory and adrenergic neurons (Habermann and Dreyer, 1986). The H_C domain plays a major role in neurospecific binding (Lalli et al., 1999), but additional regions may be involved in determining the remarkable specificity for cholinergic terminals of CNTs. There is strong evidence that polysialogangliosides (particularly G_{D1b}, G_{T1b} and G_{Q1b}) are involved (Habermann and Dreyer, 1986; Halpern and Neale, 1995) together with proteins of the presynaptic membrane (Montecucco, 1986). The gangliosides binding site(s) have been localized within the C-terminal half of H_C (H_C-C), which harbors one binding site for the oligosaccharide portion of polysialogangliosides in BoNT/A and /B, while the H_C-C of TeNT has two such binding sites (Rummel et al., 2003a, Rummel et al., 2003b, and references cited therein). In addition, the Thy-1 glycoprotein participates in the binding of TeNT to spinal cord motoneurons (Lalli et al., 2003) and synaptotagmins I and II (membrane-bound Ca^{+2}-signaling machines) in that of BoNT/B, together with gangliosides (Nishiki et al., 1996; Yowler et al., 2002; Dong et al., 2003; Rummel et al., 2004).

Both TeNT and BoNTs bind to the presynaptic membrane of α-motoneurons, but they then follow different intracellular trafficking paths. BoNTs block neuroexocytosis at peripheral terminals, whereas TeNT causes the same effect on CNS synapses of the spinal cord. These different final destinations of TeNT and BoNTs must be determined by specific coreceptors that drive them into different intracellular routes. The presence of both glycolipid and glycoprotein coreceptors is in keeping with a high affinity and specific binding of CNTs to the presynaptic membrane because multiple interactions are involved. However, the receptor molecules identified so far are not cholinergic specific, and the CNT regions and coreceptors responsible for this specificity and for steering BoNTs to the inside of cholinergic terminals and TeNT to the spinal cord via retroaxonal transport remain to be identified.

INTERNALIZATION (STEP 2 OF FIG. 4) Since the L chains of CNTs block neuroexocytosis by acting in the cytosol, at least this toxin domain must reach the cell cytosol. All available evidence indicate that CNTs do not enter the cell directly from the plasma membrane, rather they are endocytosed inside acidic intracellular compartments via a temperature- and energy-dependent process (Dolly et al., 1984; Matteoli et al., 1996). A protein coreceptor of TeNT is thought to be responsible for its inclusion in an endocytic vesicle, which moves in a retrograde direction along and inside the axon (Schwab and Thoenen, 1976; Herreros and Schiavo, 2002), whereas BoNTs protein coreceptors guide them inside vesicles that acidify within the cholinergic terminal. The TeNT-carrying vesicles reach the cell body of the motoneuron in the spinal cord and then move to dendritic terminals to release the toxin in the intersynaptic space. TeNT equilibrates between pre- and postsynaptic membranes and then binds and enters the inhibitory interneurons of the spinal cord most likely via synaptic vesicle endocytosis (Matteoli et al., 1996).

MEMBRANE TRANSLOCATION (STEP 3 OF FIG. 4) To reach the cytosol, the L chain must cross the hydrophobic barrier of the vesicle membrane, and the acidity of the lumen is essential for such a movement. CNTs have to go through a low pH step for nerve intoxication to occur (Simpson et al., 1994; Williamson and Neale, 1994). This causes a conformational change from a water-soluble "neutral" structure to an "acid" structure, with the surface exposure of hydrophobic patches, which mediate the interaction of the H and L chains with the hydrocarbon core of the lipid bilayer (Montecucco et al., 1989). Following this low pH-induced membrane insertion, BoNTs and TeNT form transmembrane ion channels in planar lipid bilayers (Koriazova and Montal, 2003, and references cited therein) and in cell membranes (Beise et al., 1994; Sheridan, 1998). Membrane translocation of bacterial protein toxins (including CNTs) is the least understood step of their mechanism of action. For BoNT/A, a chaperone activity for the H chain has been envisioned preventing the aggregation of the L chain in the acid vesicle interior and preserving an unfolded conformation during translocation, release and refolding of the L chain at the neutral pH of the cytosol (Koriazova and Montal, 2003). The release of the L chain into the cytosol requires reduction of the interchain disulfide bond (Montecucco and Schiavo, 1995).

PROTEOLYSIS OF SNARE POTEINS (STEP 4 OF FIG. 4) Once in the cytosol, CNT L chains display their catalytic activity. CNTs are remarkably specific proteases that recognize and cleave only three proteins, which form the core of the neuroexocytosis machinery (Schiavo et al., 2000; Rossetto

et al., 2001b). Vesicle-associated membrane protein (VAMP), synaptosomal associated protein of 25 kDa (SNAP-25), and syntaxin form a heterotrimeric coiled-coil complex, which juxtaposes the vesicle to the target membrane (Sutton et al., 1998) and is involved in their fusion (Chen and Scheller, 2001). VAMP is a family of proteins located on the membrane of intracellular vesicles with a C-terminal tail facing the vesicle lumen, a single transmembrane domain, and the remaining N-terminal part exposed to the cytosol (Fig. 5). Different VAMP isoforms are located on different cell vesicles, and each VAMP helps direct each vesicle to its appropriate target membrane. VAMP-1 and -2 are the isoforms mainly involved in the binding and fusion of neurotransmitter containing synaptic vesicles with the presynaptic membrane (neuroexocytosis). Syntaxin is anchored to target membranes via a C-terminal hydrophobic tail. Of the many syntaxin isoforms presently known, syntaxin 1A, 1B and 2 are the main syntaxins involved in neuroexocytosis. SNAP-25 proteins (few isoforms) are bound to the target membrane via fatty acids covalently linked to cysteine residues present in the middle of the polypeptide chain.

TeNT, BoNT/B, /D, /F and /G cleave the vesicle-associated membrane protein VAMP/synaptobrevin, at different single peptide bonds; BoNT/C cleaves both syntaxin and SNAP-25 (two proteins of the presynaptic membrane), while BoNT/A and /E cleave SNAP-25 at different sites within the COOH-terminus (reviewed in Schiavo et al. [2000] and Humeau et al. [2000]; Fig. 6). Proteolysis of one soluble N-ethylmaleimide sensitive factor-attachment protein receptor (SNARE) protein prevents fusion complex formation, or it may result in a nonfunctional complex (Hayashi et al., 1994; Pellegrini et al., 1995; Humeau et al., 2000; Fig. 5).

Strikingly, TeNT and BoNT/B cleave VAMP at the same peptide bond (Gln76-Phe77; Table 1) and yet, when injected into the animal, they cause the opposite symptoms of tetanus and botulism, respectively (Schiavo et al., 1992a; Schiavo et al., 1992b). This conclusively demonstrates that the different symptoms of the two diseases derive from different sites of intoxication rather than from a different molecular mechanism of action.

The biochemical basis of the CNTs specificity for the three SNAREs is only partially known. Experimental evidence clearly indicates that CNTs recognize a nine-residue-long motif characterized by the presence of three carboxylate residues alternated with hydrophobic and hydrophilic residues (Rossetto et al., 1994; Pellizzari et al., 1996; Washbourne et al., 1997; Vaidyanathan et al., 1999). This motif is present in two copies (V1 and V2) in VAMP and syntaxin and in four copies in SNAP-25. In addition, TeNT recognizes a positively charged cluster of residues of VAMP located C-terminal to the cleavage site (Cornille et al., 1997).

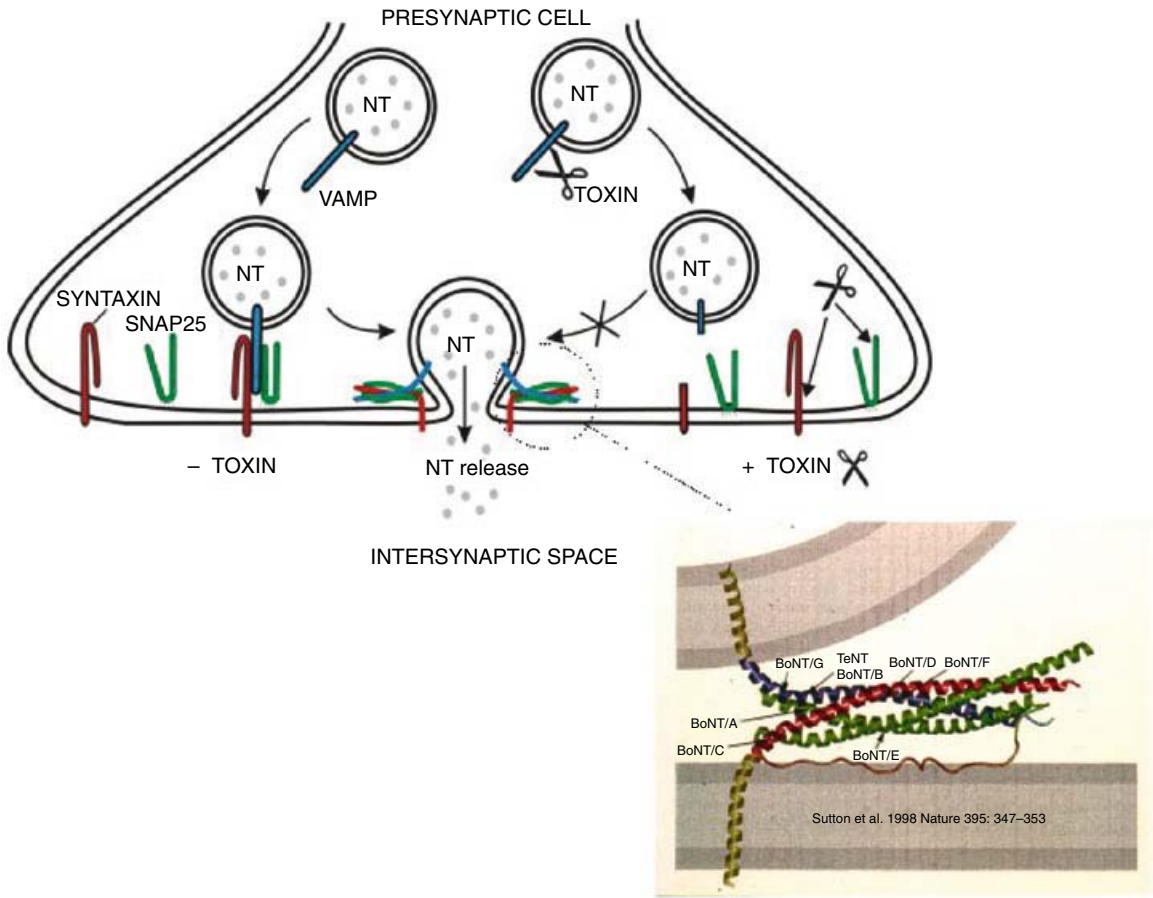
The peptide bonds hydrolyzed by each neurotoxin are reported in Table 1. Apart from TeNT and BoNT/B, each of the different CNTs cata-
Fig. 5. Schematic of a nerve terminal showing the process of the neurotransmitter (NT) release (left) and the mechanism of action of tetanus and botulinum neurotoxins (right). Neurotransmitter containing vesicles are characterized by a transmembrane protein, vesicle-associated membrane protein (VAMP), that binds specifically two proteins of the cell membrane (syntaxin and synaptosomal associated protein of 25 kDa [SNAP25]). These three proteins make a complex that forces the vesicle and cellular membranes into close contact and eventually to fuse, thus releasing the NT into the intersynaptic space. Tetanus and botulinum neurotoxins are Zn-endopeptidases that cleave VAMP, or syntaxin or SNAP25, preventing the complex formation and therefore exocytosis of NT.


Fig. 6. Schematic structure of soluble *N*-ethylmaleimide sensitive factor-attachment protein receptor (SNARE) proteins and cleavage site of tetanus neurotoxin (TeNT) and botulinum neurotoxins (BoNTs). Vesicle-associated membrane protein (VAMP) has a short C-terminal tail protruding into the vesicle lumen and a trasmembrane segment, followed by a longer cytosolic part, which is highly conserved between isoforms and species, whereas the N-terminal portion is poorly conserved and rich in prolines. Syntaxin is inserted in the plasma membrane, and most of its mass projects into the cytosol. Synaptosomal associated protein of 25 kDa (SNAP-25) is bound to the cytosolic face of presynaptic membrane via palmitoylated cysteine residues and via interactions with syntaxin. Arrows indicate the sites of cleavage of clostridial neurotoxins (CNTs). The bottom-right panel shows the crystallographic structure of the soluble *N*-ethylmaleimide sensitive factor-attachment protein receptor (SNARE) complex.

Table 1. Tetanus and botulism neurotoxins target and peptide bond specificities.[a]

Toxin type	Intracellular target	Peptide bond cleaved
		P4-P3-P2-P1—P1′-P2′-P3′-P4′
TeNT	VAMP	Gly-Ala-Ser-Gln—Phe-Glu-Thr-Ser
BoNT/A	SNAP-25	Glu-Ala-Asn-Gln—Arg-Ala-Thr-Lys
BoNT/B	VAMP	Gly-Ala-Ser-Gln—Phe-Glu-Thr-Ser
BoNT/C	Syntaxin	Asp-Thr-Lys-Lys—Ala-Val-Lys-Phe
BoNT/C	SNAP-25	Ala-Asn-Gln-Arg—Ala-Thr-Lys-Met
BoNT/D	VAMP	Arg-Asp-Gln-Lys—Leu-Ser-Glu-Leu
BoNT/E	SNAP-25	Gln-Ile-Asp-Arg—Ile-Met-Glu-Lys
BoNT/F	VAMP	Glu-Arg-Asp-Gln—Lys-Leu-Ser-Glu
BoNT/G	VAMP	Glu-Thr-Ser-Ala—Ala-Lys-Leu-Lys

Abbreviations: TeNT, tetanus neurotoxin; BoNT, botulinum neurotoxin; VAMP, vesicle-associated membrane protein; SNAP-25, synaptosomal associated protein of 25 kDa; and SNARE, soluble N-ethylmaleimide sensitive factor-attachment protein receptor.

[a]Sequences refer to human SNAREs.

lyzes the hydrolysis of a different peptide bond. Thus CNTs are well-defined tools to probe the role of their targets in different cellular processes, and finer dissections of SNARE activities can be performed on the basis of the peptide bond hydrolyzed by the different CNTs. Moreover, since the three SNAREs are not cleavable by the CNTs when they are complexed (Hayashi et al., 1994; Pellegrini et al., 1995), these neurotoxins can be used to assay the state of SNARE assembly. Although BoNT/A removes only nine residues from the SNAP-25 C-terminus, neuroexocytosis is impaired, thus indicating that this part of the molecule plays a relevant role in exocytosis.

The cleavage of the SNARE proteins by the BoNTs within the nerve cells does not cause cell death, as do other bacterial toxins (diphtheria toxin, shiga toxins, etc.). Within a time period that varies with the type of nerve, animal species, and type of BoNT, the toxin is inactivated within the nerve and new SNARE protein is synthesized leading to full functional recovery. In other words, if enough toxin has been released within the body, the loss of function of respiratory muscles and other muscles leads to death. However, in the case of milder intoxications, or if the patient is kept alive by mechanical ventilation, with time the patient will fully recover.

Botulinum Neurotoxins in Human Therapy

The demonstration that BoNTs specifically inhibit peripheral cholinergic nerve terminals and that this is followed by a complete functional recovery of the neuromuscular junction have provided the scientific basis for the rapidly growing use of BoNTs in the therapy of a variety of human diseases caused by hyperfunction of cholinergic terminals (Scott, 1989; Jankovic and Hallet, 1994). Injections of minute amounts of BoNT into the muscle(s) to be paralyzed lead to a depression of the symptoms lasting months, depending on the type of toxin used. After the first demonstration of the efficacy of BoNT/A injection in the treatment of strabismus (Scott, 1989), the therapeutic use of this neurotoxin has been extended to dystonias and other movement dysfunctions that respond to treatment based on a partial paralysis of the neuromuscular junction (Table 2). More recently, the use of BoNTs has been extended to diseases of the autonomic cholinergic nerve system such as hyperhydrosis and hypersalivation and to myofascial pain and tension and migraine headaches (Moore and Naumann, 2003). There are comparatively few side effects of the treatment with BoNT/A; the

most important one is the production of antibodies that renders the patient resistant to the toxin. In general, this occurs with the large doses of toxin necessary to weaken strong muscles within anatomical areas rich in lymph nodes such as the neck, treated for spasmodic torticollis. If there are neutralizing anti-BoNT/A antibodies, one has to switch to a different serotype. BoNT type B has been recently introduced for the treatment of cervical dystonias (Brashear et al., 1999), and very encouraging results have been obtained with BoNT/C (Eleopra et al., 1997; Eleopra et al., 2002).

Ecology of Neurotoxin-producing *Clostridia*

Clostridium tetani, BoNT-producing *Clostridia*, and other *Clostridia* are largely present in the environment in the form of spores, which are able to survive for very long periods under extreme conditions (involving heat, dryness, radiation, chemicals and oxygen). Spore germination and cell division occur only under anaerobic conditions and in the presence of the appropriate nutritional requirements. This restricts the habitat of the *Clostridium* to anaerobic, or low oxygen, areas containing sufficient amounts of organic materials. On the basis of their physiological properties (tolerance or extreme sensitivity to oxygen, and requirement of particular pH, temperature and substrate for growth or spore germination), the distribution of the different *Clostridium* species in nature is not uniform (Hippe et al., 1992). Saccharolytic *Clostridia* such as *C. butyricum* are able to grow on carbohydrates and are mainly found in decomposing vegetables and fruits. Proteolytic and gelatinolytic *C. botulinum* and *C. tetani* are preferentially associated with animal cadavers and soils or sediments rich in organic material. They can also be found in the digestive tract of healthy humans and animals, and, after death, they participate in the cadaver's decomposition.

Clostridium tetani

This ubiquitous organism is commonly found in all parts of the world. The frequency of its isolation from soil samples varies (30–42%; Smith and Williams, 1984). This variability is due to pH, temperature, moisture, and amount and type of organic materials. Thus, germination and multiplication of *C. tetani* have been observed preferentially in neutral or alkaline soil, with temperatures >20°C and humidity reaching 15% (Smith and Williams, 1984). *Clostridium tetani* shows a higher presence in southern regions, and

Table 2. Therapeutic use of botulinum neurotoxins in humans.

Disease/condition	Clinical effect	Benefit	Duration (months)
Blepharospasm	E	3+	2–4

accordingly the incidence of tetanus is higher in warmer countries than in the cooler parts of the world (Smith and Williams, 1984). This bacterium can be found in the intestine of animals but does not represent a significant part of the normal digestive flora. Different surfaces and objects contaminated with soil particles, dust or feces may contain *C. tetani*. Toxigenic strains have even been isolated within hospitals from catgut, cotton wool, dust and air samples, human skin, and wounds (Bytchenko, 1981).

BoNT-producing *Clostridia*

These organisms occur in most parts of the world in habitats that include soils as well as lake and sea sediments. However, the different toxinotypes of *C. botulinum* are not equally distributed, some being restricted to particular ecological areas. Table 3 summarizes the frequencies of isolation of the various toxinotypes in different countries. The factors responsible for the geographical distribution of the different toxinotypes are still poorly understood. Toxinotypes A and B occur more frequently in soil samples, whereas toxinotype E is more predominant in sea or lake sediments. Toxinotypes C and D appear to be obligate parasites of birds and other animals, and cadavers of people who died of botulism are a major source of these organisms. They are seldom encountered in soil samples, except in the areas where the incidence of animal botulism is high (Smith and Williams, 1984). *Clostridium botulinum* is not usually found in the digestive tract of healthy humans, but it can be found in that of animals, particularly *C. botulinum* C and D. *Clostridium butyricum* and *C. baratii* are very widespread in the environment and are present as well within animals (Cato et al., 1986); the first two neurotoxigenic *C. butyricum* strains were isolated from infant botulism (Aureli et al., 1986).

Botulinum Neurotoxins in Food

In general, the contamination of fish and other aquatic animals by *C. botulinum* reflects that of the sediments of the respective geographic areas. The incidence of *C. botulinum* depends on these areas and on the type of fish: gills and intestines are the most heavily contaminated parts. *Clostridium botulinum* E does not multiply in the intestine of living fish, but after death, the bacterium can grow and produce BoNT. Dead fish in the sediments contribute to the persistence and multiplication of *C. botulinum* in the aquatic environment (Dodds, 1993a) and to large

Table 3. Frequencies of isolation of the various toxinotypes in different countries.

outbreaks of botulism caused by the ingestion of dead fish containing high titer of BoNT, producing an ever-increasing chain reaction of disease spread (Eklund et al., 1982).

Contamination of meat with *C. botulinum* is less frequent than that of fish, and toxinotypes A and B are usually predominant, followed by C, and more rarely by E. Fruits and vegetables may be contaminated by *C. botulinum* as a result of soil contamination. Honey may contain *C. botulinum*, but the level of contamination is usually low (1–10 spores per kg). However, honey samples associated with infant botulism contained as many as 10^3–10^4 spores per kg. The presence of *C. botulinum* in other foods (such as dairy products or prepared foods [boil-in-bag foods, vacuum-packed foods, pressurized foods, dehydrated and freeze-dried foods]) is very rare (Dodds, 1993a).

Tetanus

The Disease

The first record of tetanus coincides with the beginning of medical literature, when Hippocrates in the Greek isle of Kos described the case of a sailor who developed a spasmodic generalized contracture of skeletal muscles, which he termed "tetanus" (τεταηοσ in Greek means contraction). Generalized tetanus is the most common form of the disease and the portal of entry in 80% of cases is a minor wound or skin scratch. Between the time of injury and the first symptoms, there is a lag phase varying between few days up to four weeks. Tetanus usually begins with a characteristic facial trismus (lockjaw or "risus sardonicus") with difficulty in swallowing and neck stiffness (Bleck, 1989). With time, the muscle paralysis extends downwards to the muscles of the trunk, abdomen and legs. The typical tetanic seizure is characterized by a sudden burst of tonic contraction of skeletal muscles causing opisthotonos, flexion and adduction of the arms, and extension of the lower extremities. The seizure is very painful and can be triggered by minor stimuli such as a small light. Later on, autonomic symptoms develop including alterations of blood pressure and of the cardiac rhythm, and sweating. Glottal and laryngeal spasm may develop and cause cyanosis and asphyxia.

A milder form of the disease is local tetanus, with rigidity of the group of muscles close to the site of injury and spreading of TeNT. This local tetanus may persist for a considerable period without further developments or it may progress to generalized tetanus. It is due to dysfunction of interneurons that inhibit the alpha motor neu-

rons of the affected muscles without further spread through the CNS.

Owing to the benefit of vaccination with the very immunogenic tetanus toxoid (formaldehyde-treated and inactivated tetanus toxin), tetanus has almost disappeared from the more developed countries, but it still takes hundreds of thousand of lives in those regions of the world where vaccination is not practiced (Galazka and Gasse, 1995). Here, the major form of tetanus is tetanus neonatorum, which develops after the umbilical cord of babies born to nonimmunized mothers is cut. In fact, tools contaminated with spores are often employed and rags, often soiled with animal feces, are used as dressing, thus increasing the possibility of contamination.

Tetanus is often fatal; death follows body exhaustion and is usually due to respiratory or heart failure (Bleck, 1989). Mortality has decreased in the more developed parts of the world owing to modern intensive care techniques, but it is still high because of the usually advanced age of patients and because their respiration has to be mechanically assisted for long periods, which in turn risks development of pulmonary infections.

Epidemiology of Tetanus

Tetanus is almost invariably associated with infection of necrotic wounds. Tetanus from ingestion of preformed toxin in food or by absorption of tetanus toxin produced by *C. tetani* in the intestine has not been reported, though this organism has been found in human and animal feces (Smith and Williams, 1984), and it can grow and produce toxin in the intestinal tract of germ-free rats (Wells and Balish, 1983). As an anaerobic bacterium, *C. tetani* does not grow in the normal oxygenated tissue and some degree of tissue necrosis is necessary for spore germination and bacterial outgrowth. Concomitant infection by other bacteria may also provide conditions suitable for the growth of *C. tetani* (Smith and Williams, 1984).

Tetanus is frequent in subtropical and tropical countries with poor hygienic conditions and where antitetanus vaccination is not performed or the vaccination protocol is only partially achieved. Neonatal tetanus is currently the most represented form of tetanus in the world (Galazka and Gasse, 1995). The incidence of tetanus in countries where vaccination is a common practice is very low (annual incidence of 0.2 per million) and always involves aged persons whose level of anti-TeNT antibodies has fallen with age. A single booster injection in adulthood is sufficient to bring the level of antitoxin antibodies to

a fully protective level, and this procedure is highly recommended.

Domestic animals can contract tetanus, and the disease is frequent and severe in horses. The susceptibility to TeNT depends on the animal species. Birds are relatively resistant and cold-blooded animals quite resistant. The most susceptible animal species, in decreasing order, are horse, sheep, goat, mouse, rat, rabbit, monkey, guinea pig, dog, cat, pigeon, and chicken (Payling-Wright 1955; Dezfulian, 1989). The different susceptibility to tetanus can be attributed to many factors including variable amounts and nature of receptors in the peripheral and/or central nervous system. Environmental factors may also play a role. For example, frogs are much more resistant to TeNT at 15°C than at 23°C, most likely because endocytosis of the toxin is reduced by low temperature.

Botulism

Human Botulism

Unlike tetanus, botulism follows the ingestion of foods containing preformed BoNT, and very rarely is it caused by wound infections. Four forms of botulism are recognized according to the mode of acquisition.

FOODBORNE BOTULISM The cause is ingestion of food maintained under anaerobic conditions, which permit the growth of *C. botulinum* with the production of sufficient amounts of BoNT. This is the most common form of disease in adults. Usually, several persons are intoxicated at the same time by sharing contaminated food. Usually BoNT/A, /B and /E and much less frequently types F, C or D are involved (Hatheway, 1993b). BoNT are released as complexes with accessory nontoxic proteins, which greatly increase the resistance of BoNTs within the gut, where the toxin is adsorbed and enters the general circulation to reach its neuronal target sites (Maksymowych et al., 1999). All the symptoms of botulism can be ascribed to the blockade of the peripheral cholinergic nerve terminals (in both skeletal muscle and autonomic ganglia) with ensuing flaccid paralysis of the muscles and autonomic dysfunctions (Tacket and Rogawski, 1989). BoNTs affect initially head nerve terminals causing diplopia or visual blurring, ptosis, dysphagia, facial paralysis, reduced salivation and lacrimation. The paralysis then progresses down to the muscles of the trunk, including the respiratory, visceral and then limb muscles.

The seriousness of the illness depends on the amount and type of BoNT. Death follows the blockade of respiratory muscles, but if the

patient is mechanically ventilated, with time he will recover completely following the metabolism of the toxin and the resynthesis of intracellular substrates. In general, botulism is much less dangerous than tetanus because, in most cases, the amount of toxin that reaches the general circulation is not sufficient to block respiration; it is believed that most cases of BoNT intoxication fail to attain clinical relevance and go unnoticed. Type A botulism is more dangerous than types B and E, and its symptoms persist much longer.

The incidence and the types of botulism depend on the occurence of *C. botulinum* in the environment and subsequently in foods and in cooking practices. The geographical distribution of the different types of botulism corresponds to the distribution of the different toxinotypes of *C. botulinum* in the environment. Thus, type E botulism is mainly found in the colder regions of the northern hemisphere and aquatic animals are usually affected (Hauschild, 1993), and types A and B botulism occur generally in the temperate countries. Most botulism outbreaks are caused by home prepared or stored/fermented food, while contamination of foods prepared by food industries is very rare (Hauschild, 1993).

INFANT BOTULISM The cause is ingestion of spores of toxigenic *Clostridia* that germinate, multiply, and produce BoNT in the intestinal tract. This is possible only when the normal intestinal flora have not yet been established, and in fact most cases of infant botulism develop in babies (1–6 months of age at the onset; Arnon, 1989). The minimum infective dose for human infants has been estimated to be 10–100 spores (Arnon, 1989). Moderate to high BoNT levels ($10–10^5$ times the mouse lethal dose per g) and viable *C. botulinum* are recovered from stools of affected infants for a long period after the onset of the symptoms. Therefore, infant botulism is a toxo-infection rather than an intoxication (as in adult botulism). The affected infants present with constipation, weak sucking, hypotonia and ptosis. In the more severe cases, the patient becomes lethargic and loses head control. The disease progresses to a flaccid paralysis, which may extend to respiratory muscles with arrest. Again, type A is generally more dangerous than type B or E, and the recovery time is accordingly longer (Arnon, 1989). Infant botulism has been identified in many developed countries, but most cases were recorded in the United States, particularly in California. It is presumed that contamination occurs with *C. botulinum* spores from the environment, and honey feeding has been frequently implicated (Arnon, 1989).

A new category of botulism of undetermined etiology has been proposed to occur in patients older than 1 year of age and to which no association with food or wounds has been recognized as the source of toxin. *Clostridium botulinum* and its toxin have been evidenced in these patients' stools for a long period (3 weeks and in some cases up to 6 months; Hatheway, 1993a). It has been concluded that this form of botulism in adults (as in infant botulism) follows colonization of the digestive tract by *C. botulinum* with local production of BoNT (Chia et al., 1986; McCroskey and Hatheway, 1988).

WOUND BOTULISM Like tetanus, this form of botulism results from colonization of a wound with *C. botulinum* and subsequent local production of BoNT. However, wound botulism is much less frequent than tetanus, despite the fact that the general population is not immunized against BoNT, indicating that *C. botulinum* strains have a low ability to grow in wounds compared to *C. tetani*.

ANIMAL BOTULISM Botulism is rather common among domestic and wild animals, and types C and D are involved in addition to A, B and E. Botulism of domestic animals causes economic losses, but it is also a risk factor of transmission to humans. Animal botulism can be contracted by eating the carcass or chewing on bones contaminated with BoNT, by drinking water from contaminated ponds, or by ingestion of forage poisoned by diffusion of BoNT from carcass decomposition of small animals or birds. Among fish and birds, botulism outbreak can involve millions of individuals. The disease may have the appearance of an epidemic because insect larvae that grow in the decomposing cadaver become full of BoNT, which is innocuous to insects. Since healthy birds and fish are eager for larvae, they become intoxicated and die, providing a rich anaerobic medium for the growth of *Clostridia* and for the deposition of eggs by insects. A self-perpetuating cycle is thus obtained and rapidly many individuals can die, particularly when the animal population is dense as it is in farms. Where botulism is common, animals often carry *C. botulinum* in their digestive tract, which rapidly grows in the cadavers and becomes highly toxic and rich in spores (Smith and Sugiyama, 1988; Dodds, 1993b).

CHAPTER 1.2.22

The Enterotoxic Clostridia

BRUCE A. MCCLANE, FRANCISCO A. UZAL, MARIANO E. FERNANDEZ MIYAKAWA,
DAVID LYERLY AND TRACY WILKINS

Introduction to the Enterotoxic Clostridia

The anaerobic, nutrient-rich conditions of the mammalian gastrointestinal (GI) tract provide a relatively attractive niche for many clostridia. Several of those clostridial species also produce toxins with potent activity on the GI tract, enabling them to cause human and/or veterinary enteric diseases (Table 1).

Clostridial enteric diseases vary considerably (as described in the Clinical Disease and Epidemiology sections of this chapter) but can be quite common and severe. Collectively, these infections place a major economic burden on human and veterinary medicine, draining billions of dollars per year from the economy.

This chapter focuses on the two most important enterotoxic clostridial species for human and veterinary enteric diseases, i.e., *Clostridium perfringens* and *Clostridium difficile*.

Clostridium perfringens

Introduction

Clostridium perfringens has a ubiquitous environmental distribution, including a presence in the normal GI flora of humans and domestic animals. Under favorable conditions, this bacterium can cause a wide array of enteric and histotoxic infections. This chapter focuses on the medical and veterinary enteric diseases caused by *C. perfringens*; the histotoxic infections caused by this bacterium are discussed in a separate chapter.

Historical Perspective

Clostridium perfringens has been linked to human GI disease since the mid-1940s, when McClung first noted this bacterium's ability to cause food poisoning (McDonel, 1986). This tentative association was confirmed by the classic studies of Hobbs during the 1950s (McDonel,

1986). In the late 1940s, *C. perfringens* also became associated with outbreaks of darmbrand (enteritis necroticans) in post-war Germany (Lawrence, 1997). The early 1980s saw the first linkage of *C. perfringens* with human nonfood-borne GI diseases (Borriello et al., 1984; Borriello, 1995).

The association of *C. perfringens* with veterinary enteric disease occurred even earlier, with initial reports surfacing in the 1920s and early 1930s (Songer, 1996). Appreciation of the full scope of *C. perfringens* veterinary diseases increases to this day.

Phylogeny

The genus *Clostridium* consists of nearly 150 phylogenetically heterogeneous species that do not represent a coherent taxon (Stackebrandt, 1997). Using 16S ribosomal RNA sequence analyses, 19 different clostridial species clusters have been defined (Stackebrandt, 1997; Stackebrandt et al., 1999). Along with most other pathogenic clostridial species (except *C. difficile*), *C. perfringens* belongs to phylogenetic cluster I, which is considered the core cluster of the genus *Clostridium*. Within that core cluster, *C. perfringens* belongs to the same Ia subcluster that also includes *Clostridium botulinum*.

Taxonomy

Clostridium perfringens is a Gram-positive, nonmotile, short-to-intermediate sized rod, often with a "box-car shape" (Fig. 1). This bacterium is anaerobic, as it does not grow on plates incubated under atmospheric oxygen conditions. However, *C. perfringens* is not killed quickly when exposed to air and grows after only modest reductions in environmental oxidation-reduction (E_h) conditions, perhaps because this bacterium produces relatively high amounts of superoxide dismutase (Mitchell, 2001). *Clostridium perfringens* forms spores, although sporulation is difficult to demonstrate with many isolates (particularly fresh clinical isolates).

Table 1. Major clostridial species causing human and/or veterinary enteric disease.

Species	Associated diseases	Toxins involved
C. colinum	Enterotoxemia[a] (chickens); ulcerative colitis of psittacines	?
C. difficile	Antibiotic-associated diarrhea and pseudomembranous colitis of humans; veterinary diarrheas (dogs) and necrotizing enteritis (foals)	Toxin A; toxin B; and CDT[b] (ι toxin)
C. perfringens	*C. perfringens* type A food poisoning of humans; necrotizing enteritis of humans (PigBel); antibiotic-associated and sporadic diarrhea of humans; animal enterotoxemias	*C. perfringens* enterotoxin (CPE), α toxin, β toxin, β2 toxin, ε toxin, and ι toxin[c]
C. septicum	Neutropenic enterocolitis of humans and animal enterotoxemias	α toxin
C. sordellii	Animal enterotoxemias	Lethal toxin
C. spiroforme	Animal enterotoxemias (rabbits)	ι toxin

[a]The term "enterotoxemia" is used generically in this table to indicate any serious animal infection where toxin is produced in the intestines.
[b]*Clostridium difficile* actin-specific ADP-ribosyltransferase.
[c]See Tables 2 and 3 and text for more details.

Fig. 1. Photomicrograph of Gram-stained *C. perfringens*. Note the "box car" shape. 1000× magnification.

Table 2. *Clostridium perfringens* toxin typing classification scheme.

Type[a]	Toxin produced			
	α	β	ε	ι
A	+	−	−	−
B	+	+	+	−
C	+	+	−	−
D	+	−	+	−
E	+	−	−	+

Symbols: +, produced; and −, not produced.
[a]*C. perfringens* type.

Colonies of *C. perfringens* usually reach 1–3 mm after overnight anerobic incubation on blood agar but often become much larger on longer incubation. Owing to production of hemolytic toxins (α-toxin and θ-toxin, also known as "perfringolysin O"), this bacterium typically produces a characteristic double zone of hemolysis on blood agar plates. Alpha toxin also has phospholipase C/lecithinase activity, so *C. perfringens* colonies usually exhibit lecithinase activity when grown on egg yolk agar. This bacterium causes a "stormy fermentation" of milk, hydrolyzes gelatin, ferments lactose, and reduces nitrate.

Clostridium perfringens produces a capsule whose carbohydrate composition varies between isolates. Capsular serotyping approaches have been developed to exploit this variability for distinguishing between *C. perfringens* isolates (Stringer, 1985). These capsular serotyping approaches were successfully employed during the 1950s–1980s to investigate *C. perfringens* type A food poisoning outbreaks in the United Kingdom (Stringer, 1985). However, capsular serotyping proved much less effective for investigating *C. perfringens* type A food poisoning outbreaks in the United States and Japan (where many isolates could not be typed with existing antisera), so this technique is less commonly used today.

This bacterium is a prolific toxin producer, with an intimidating arsenal consisting of at least 14 toxins (McDonel, 1986). However, only certain toxin combinations are expressed by individual isolates, forming the basis of a commonly used toxin-typing scheme for differentiating between *C. perfringens* isolates (McDonel, 1986). This toxin typing approach classifies *C. perfringens* isolates into types A–E on the basis of their production of four toxins: α, β, τ and toxins (Table 2).

This diversity of toxin expression among isolates helps explain why *C. perfringens* causes such a wide array of diseases, ranging from enteric to histotoxic infections. In that regard,

the toxin typing scheme shown in Table 2 is particularly important for understanding enteric pathogenesis, as each *C. perfringens* toxin type is associated with certain GI diseases (see Table 3).

In addition to the four typing toxins, other toxins are also clearly important for *C. perfringens* virulence. Inspection of Table 3 indicates that isolates producing *Clostridium perfringens* enterotoxin (CPE) and β2 toxin are important causes of enteric disease. Although biomedically important, only ~1–5% of all *C. perfringens* isolates, mainly belonging to type A, produce CPE (McClane, 2001a). Interestingly, nearly all type E isolates carry a defective *cpe* gene (Billington et al., 1998; see Genetics). The β2 toxin gene (*cpb*2) is more commonly distributed and can be found in any toxin type but is especially common in type E isolates (Bueschel et al., 2003).

Habitat/Ecology

The widespread environmental distribution of *Clostridium perfringens* includes a presence in soils, foods, sewage, and the GI tract of healthy or diseased humans and domestic animals. In such non-disease settings, most *C. perfringens* isolates are classified as type A and *cpe*-negative; understanding of the normal ecologic niche for the isolates causing most cases of human and veterinary enteric diseases (i.e., type A isolates producing CPE, type B, type C, type D or type E isolates) is currently only limited.

Isolation and Identification

Several selective media are commonly used for isolating *C. perfringens* from soil, foods or feces; one such selective medium is TSC (tryptose-sulfite-cycloserine) agar. *Clostridium perfringens* can be isolated by streaking a sample onto a TSC agar plate, which is then incubated anaerobically (e.g., in a Gas Pak jar) for ~18 hours. *Clostridium perfringens* colonies should appear black on this agar owing to sulfite reduction (Fig. 2A). However, perhaps 50% of all *C. perfringens* colonies appear white on TSC agar plates, and even when present initially, the black colony color often rapidly fades when examined in air. To increase the identification power of TSC agar, it is helpful to incorporate egg yolk agar into the medium. Precipitation around a colony (whether white or black) growing on TSC-containing egg yolk agar is suggestive of *C. perfringens*, which typically exhibits lecithinase activity from the phospholipase C activity of α toxin. An alternative medium commonly used for *C. perfringens* isolation is sheep blood agar containing neomycin. On this medium, most *C. perfringens* colonies are surrounded by a distinctive double zone of hemolysis due to the hemolytic activities of α and θ (perfringolysin O) toxins (Fig. 2B).

For confirmatory identification of presumptive *C. perfringens* isolates, a number of approaches can be used. Commonly used tests include evaluating whether putative isolates ferment lactose, hydrolyze gelatin, and reduce nitrate. This bacterium is also indole-negative, catalase-negative, and negative for motility in an agar deep. Gas

Table 3. Association of *C. perfringens* types with human and veterinary diseases.

Type	Major toxins	Representative diseases
A	α	Human wound infections (e.g., gas gangrene or clostridial myonecrosis), necrotic enteritis in fowls, ulcerative abomasitis and necro-hemorrhagic enteritis in cattle (not confirmed), enterotoxemia[a] in lambs and goat kids (not confirmed in goats), mild necrotizing enteritis in piglets, and enterotoxemia in South American camelides
	α, CPE	Human food poisoning, human nonfoodborne GI diseases, and veterinary diarrhea (particularly dogs, pigs, and foals)
	α, β2	Porcine GI disease, and cattle enterotoxemia (not confirmed)
B	α, β, ε	Dysentery and hemorrhagic enteritis in lambs and goat kids (not confirmed in adult goats), and biodefense concerns?
C	α, β	Human necrotizing enteritis (PigBel), necrotic enteritis in foals, hemorrhagic or necrotic enterotoxemias in neonatal pigs, calves, goats (not confirmed), foals, enterotoxemia (struck) in adult sheep, and enteritis in dogs, chickens and South American camelides
	α, β, β2	Porcine GI disease
D	α, ε	Enterotoxemia in sheep, goats (pulpy kidney disease) and cattle (not confirmed), and biodefense concerns?
E	α, τ	Rabbit, canine, bovine, ovine enterotoxemias

Abbreviations: CPE, *Clostridium perfringens* enterotoxin; and GI, gastrointestinal.
[a]The term "enterotoxemia" is used generically in this table to indicate serious GI animal infections where toxin(s) is produced in the intestines.
Fig. 2. Growth of *C. perfringens* on differential and selective media. A) Tryptose sulfite cycloserine (TSC) with egg yolk agar plate; note the presence of the black colonies and precipitation surrounding the colonies, and B) Sheep blood agar with neomycin; note the double zone of hemolysis surrounding the colonies.

chromatography can be used for identification of *C. perfringens*, but this approach requires more expertise, equipment, and time than biochemical identification approaches.

Preservation

Clostridium perfringens typically remains viable when stored for ~1 week at 4°C in liquid medium (such as fluid thioglycollate) or when stored frozen at –20°C for ~2 weeks. If an isolate sporulates in cooked meat medium, those cooked meat spore cultures usually remain viable for years (particularly if stored at –20°C). Other long-term (several months to many years) storage approaches include storage of vegetative cells in 50% glycerol at –80°C, or storage of lyophilized cultures (suspended in skim milk) at 4°C.

Physiology

Traditionally, *C. perfringens* has been considered a member of the saccharolytic clostridia, as it utilizes for growth a variety of carbohydrates including glucose, fructose, galactose, glycogen, lactose, maltose, mannose, raffinose, starch and sucrose. However, recent genomic analyses suggest that *C. perfringens* should also be able to ferment certain amino acids, including serine and threonine (Shimizu et al., 2002).

With respect to carbohydrate utilization for energy (Gottschalk, 1979), *C. perfringens* first converts more complex carbohydrates into simple sugars (e.g., hexoses) using degradative enzymes such as amylase. These simple sugars are then phosphorylated and taken up via phosphotransferase systems; once present inside the cell, the hexose phosphates are fermented by a classical butyric acid fermentation pathway, being first degraded via the Emden-Meyerhoff pathway to pyruvate, which is then converted to acetyl-CoA using pyruvate-ferredoxin oxidoreductase. This reaction also produces CO_2 and reduced ferredoxin, which is then oxidized (via hydrogenase) to release free hydrogen gas. The CO_2 and H_2 gases resulting from *C. perfringens* fermentations are often readily apparent as gas pockets in muscle tissue during gas gangrene. Acetyl-CoA produced by pyruvate-ferredoxin oxidoreductase is further converted by *C. perfringens* into ethanol, acetate and butyrate. The final fermentation balance (amounts formed in mol/100 mol of glucose fermented) for *C. perfringens* is 34 mol of butyrate, 60 mol of acetate, 33 mol of lactate, 176 mol of CO_2, 214 mol of H_2 and 26 mol of ethanol. The reliance of *C. perfringens* on fermentations to obtain energy can be attributed to the absence of cytochromes and tricarboxylic acid cycle (TCA) cycle enzymes in this bacterium (Shimizu et al., 2002). Despite its reliance upon fermentation for energy, *C. perfringens* has an exceptionally fast doubling time of as little as ~10 min.

Genomic analyses (Shimizu et al., 2002) indicated that, while the *Clostridium acetobutyliticum* genome encodes a complete set of genes for synthesizing amino acids, the genome of *C. perfringens* strain 13 lacks many amino acid biosynthesis genes (including the genes encoding enzymes involved in biosynthesis of arginine, aromatic amino acids, branched chain amino acids, glutamate, histidine, lysine, methionine, serine and threonine). The absence of these amino acid synthesis genes could indicate that *C. perfringens* cannot grow in environments where the amino acid supply is limiting.

Many *C. perfringens* isolates form spores, which can contribute to disease transmission of both histotoxic infections and food poisoning outbreaks. Furthermore, *C. perfringens* enterotoxin (CPE), which is responsible for the symptoms of CPE-associated human and veterinary gastrointestinal diseases, is produced only during

sporulation (McClane, 2001a). Interestingly, *C. perfringens* strain 13 genomic analyses failed to detect ~80 sporulation or germination genes present in the well-studied sporeforming bacterium *Bacillus subtilis* (Shimizu et al., 2002). These missing genes mostly encode spore coat proteins or germination-related proteins; genes encoding sporulation-associated σ factors and other stage-specific sporulation proteins are generally present in the strain 13 genome. As also previously determined for the *C. acetobutyliticum* genome (Nolling et al., 2001), strain 13 does not encode the phosphorelay system responsible for initiating sporulation in *B. subtilis* (Shimizu et al., 2002). Assuming these strain 13 findings hold true for other *C. perfringens* isolates, important differences apparently exist between the sporulation and germination processes of *C. perfringens* vs. *B. subtilis*.

Genomic analyses also revealed that *C. perfringens* strain 13 carries a large number of classical two-component regulatory systems for responding to environmental changes (Shimizu et al., 2002). Of those, only the VirR/VirS system has been extensively studied (Lyristis et al., 1994; Shimizu et al., 1994; Ba-Thein et al., 1996; Banu et al., 2000; Cheung and Rood, 2000; Ohtani et al., 2003). The VirR/VirS system plays an important role in *C. perfringens* histotoxic infections by regulating expression of α and θ toxins. As discussed later in the Toxins section of this chapter, this two-component system also probably contributes to some *C. perfringens* enteric diseases. Specifically, VirR/VirS can regulate expression of β2 toxin (Ohtani et al., 2003); whether this two-component system plays any role in regulating expression of other toxins (β, CPE, or τ toxins) involved in *C. perfringens* enteric diseases has not yet been evaluated.

Genetics

The chromosome of *C. perfringens* strain 13 is ~3.0 Mb, has a G+C content of only 28.6%, and encodes ~2.700 open reading frames (ORFs; Shimizu et al., 2002). By comparison, the ~3.7-Mb chromosome of *C. acetobutylicum* encodes ~3700 ORFs (Nolling et al., 2001). The smaller size of the *C. perfringens* strain 13 chromosome apparently renders this isolate deficient in certain metabolic pathways, such as amino acid synthesis (Shimizu et al., 2002). Whether these deficiencies are unique to strain 13 or also hold true for other *C. perfringens* isolates will soon become apparent from ongoing genome sequencing studies of two additional *C. perfringens* isolates. However, it is already clear that some *C. perfringens* isolates have much larger chromosomes (up to ~3.7 Mb) than the strain 13 chromosome (Cole and Canard, 1997).

Clostridium perfringens α toxin and perfringolysin O (a member of the streptolysin O pore-forming toxin family) are both important for histotoxic infections and are both chromosomally encoded (Canard et al., 1992; Awad et al., 1995). In contrast, most *C. perfringens* toxins linked to enteric disease (CPE, β, β2, and τ toxins) can be plasmid-encoded (Cornillot et al., 1995; Gibert et al., 1997; Collie and McClane, 1998a; Rood, 1998; Sparks et al., 2001; Miyamoto et al., 2002; Shimizu et al., 2002). With the exception of the 54-kb plasmid pCP13, which carries a β2 toxin gene in strain 13 (Shimizu et al., 2002), *C. perfringens* virulence plasmids have not yet been sequenced.

Accumulating evidence indicates that at least some virulence plasmids carrying toxin genes can horizontally transfer between *C. perfringens* isolates. For example, studies have demonstrated (Billington et al., 1998) that most, if not all, type E isolates lack clonal relationships yet carry a virulence plasmid containing an identically defective *cpe* gene (along with functional *iap* and *ibp* genes encoding τ toxin). Definitive evidence for horizontal transfer of a *C. perfringens* virulence plasmid was provided by recent mating studies clearly demonstrating transfer of a *cpe* plasmid between *C. perfringens* type A isolates (Brynestad et al., 2001). Transfer of *cpe* plasmids requires physical contact between the donor and recipients and is not affected by the presence of extracellular DNase. These observations suggest the involvement of a conjugative transfer process, although the conjugation machinery of *C. perfringens* has not yet been studied.

Transposons may also contribute to virulence gene movement in *C. perfringens*. Brynestad et al. reported that the chromosomal *cpe* gene of food poisoning isolate NCTC8239 is flanked by IS*1470* elements (Brynestad et al., 1997). From that observation, it was proposed that the NCTC8239 *cpe* gene is present on an ~6.3-kb transposon with terminal IS*1470* elements (Brynestad et al., 1997). Excision and circularization of *cpe*-containing genetic elements from the NCTC8239 chromosome was later detected; those excised elements could facilitate *cpe* gene movement (Brynestad and Granum, 1999).

Several approaches used by *C. perfringens* for regulating its virulence gene expression are also commonly employed by other Gram-positive pathogens. For example, *C. perfringens* regulates α, θ, β2 and κ toxin expression through a VirR/VirS two-component regulatory system (Lyristis et al., 1994; Shimizu et al., 1994; Ba-Thein et al., 1996; Banu et al., 2000; Cheung and Rood, 2000; Ohtani et al., 2003). This VirR-VirS regulation can be mediated through VR-RNA (Ohtani et al., 2003), a regulatory RNA (regulatory RNAs are another emerging theme for virulence gene

regulation by Gram-positive pathogens). However, *C. perfringens* also uses some relatively unusual regulatory mechanisms to regulate its virulence gene expression. For example, CPE expression during sporulation apparently involves sporulation-associated alternative σ factors (Zhao and Melville, 1998).

Phages have been identified in *C. perfringens* (Zimmer et al., 2002), but their role (if any) in virulence gene transfer is unclear at present.

Clostridium Perfringens Toxins Involved in Enteric Pathogenesis

While other *C. perfringens* toxins may also contribute to the pathogenesis of enteric disease, this section will discuss the five *C. perfringens* toxins most clearly implicated, to date, in enteric pathogenesis.

CLOSTRIDIUM PERFRINGENS ENTEROTOXIN (CPE)

Introduction In the early 1970s, Duncan's and Hauschild's groups purified CPE and demonstrated that this toxin is a 35-kDa polypeptide with heat-labile biologic activity (McDonel, 1986). CPE was later shown to lack homology with other known proteins, except for some limited homology (of unknown significance) with several nonneurotoxic proteins made by *C. botulinum* (Melville et al., 1997).

Genetics The gene *cpe* encoding this enterotoxin can be present on either the chromosome (where it may be part of Tn*5565*, a putative 6.5-kb transposon with terminal IS*1470* repeats) or on a large plasmid (Cornillot et al., 1995; Brynestad et al., 1997; Collie and McClane, 1998a; Brynestad and Granum, 1999; Sparks et al., 2001; Miyamoto et al., 2002). No single isolate has yet been found that carries both chromosomal and plasmid-borne *cpe* genes. The *cpe* plasmid of isolate F4969 can transfer via conjugation (Brynestad et al., 2001).

Interestingly, CPE-positive type A isolates causing food poisoning usually carry a chromosomal *cpe* gene, while the CPE-positive type A isolates causing nonfoodborne human GI diseases typically carry a plasmid *cpe* gene (Cornillot et al., 1995; Collie and McClane, 1998a; Collie et al., 1998b; Sparks et al., 2001; Wen et al., 2003). Possible reasons for these strong *cpe* genotype disease associations are now emerging. For example, both cells and spores of chromosomal *cpe* isolates exhibit much stronger heat resistance than the cells and spores of plasmid *cpe* isolates (Sarker et al., 2000). Thus, it is more likely for those heat-resistant, chromosomal *cpe* isolates to cause a food poisoning typically

spread via cooked meat products. Furthermore, the demonstrated ability of at least some *cpe* plasmids to transfer between *C. perfringens* type A isolates (Brynestad et al., 2001) might help initiate the CPE-associated nonfoodborne diseases. Unlike *C. perfringens* type A food poisoning, which is thought to result from ingestion of large numbers of *C. perfringens* vegetative cells present in grossly-contaminated foods (McClane, 2001a), CPE-associated nonfoodborne diseases appear to be caused by ingestion of only a low infecting dose of *C. perfringens* cells (Borriello et al., 1985c; Borriello, 1995). Thus, it should help establish disease for those few infecting isolates to transfer their *cpe* plasmid to normal flora, *cpe*-negative *C. perfringens* isolates. This putative in vivo transfer of the *cpe* plasmid to normal flora strains, which are presumably under selective pressure to colonize the GI tract, could also help explain why symptoms of CPE-associated nonfoodborne human GI diseases persist longer than those of *C. perfringens* type A food poisoning, which involves only exogenous strains probably not well-suited for intestinal colonization.

Significant organizational differences exist between the arrangements of plasmid vs. chromosomal *cpe* loci in type A isolates (Miyamoto et al., 2002; Fig. 3). These organizational differences do not affect the regulation of CPE expression, as all *cpe*-positive isolates express the enterotoxin only during sporulation (Collie et al., 1998b). The sporulation-associated nature of CPE expression is mediated at the transcriptional level (Melville et al., 1994; Czeczulin et al., 1996; Zhao and Melville, 1998) and apparently involves three highly conserved promoters located immediately upstream of the *cpe* ORF (Zhao and Melville, 1998). These *cpe* transcriptional start sites share homology with SigE- and SigK-dependent promoters, which appear important since SigE and SigK 1) are encoded by the *C. perfringens* chromosome (Shimizu et al., 2002), and 2) perform gene regulatory functions in sporulating *B. subtilis* mother cells (Zhao and Melville, 1998).

Whether carrying a chromosomal or plasmid *cpe* gene, isolates often produce extremely large amounts of the enterotoxin. CPE can represent >15% of the total protein inside a sporulating cell (Czeczulin et al., 1993; Collie et al., 1998b). The abundant expression of CPE by these sporulating cells could result, at least in part, from message stability, as older studies suggest that *cpe* mRNA has an exceptionally stable half-life of ~45 min (Labbe and Duncan, 1977). This unusual message stability could be mediated, at least in part, by the presence of a stem-loop structure, followed by an oligo T tract, downstream of the *cpe* termination codon (Czeczulin

et al., 1993); that downstream loop also likely functions as a ρ-independent transcriptional terminator (Czeczulin et al., 1993).

Mechanism of Action CPE has lethal (LD_{50} [50% lethal dose] via i.v. route = 1 µg/mouse), cytotoxic, and enterotoxic activities, as well as the ability to cause intestinal histopathologic damage. A comprehensive model depicting the current understanding of CPE action is shown in Figure 4 and will now be briefly explained.

At pathophysiologic concentrations, CPE first binds to protein receptors (McClane and McDonel, 1981). Some recent experiments

(Katahira et al., 1997a; Katahira et al., 1997b; Fujita et al., 2000) suggest the CPE receptor(s) might include certain claudins, which are a large (>20 members) family of ~22-kDa proteins that serve structurally important roles in epithelial tight junctions (TJs). In those recent studies, a series of rat fibroblasts, which do not normally express any claudins or naturally bind or respond to CPE, were transfected to express a single claudin. Expression of claudin-3, -4, -6, -7, -8, or -14 (but not claudins-1, -2, -5 or -10) was sufficient to convert those fibroblast transfectants to CPE-sensitivity, suggesting those particular claudins could be CPE receptors. However, this conclu-

sion remains tentative since direct interactions between CPE and claudins have not yet been demonstrated in enterocytes or cultured enterocyte-like cells (such as human Caco-2 cells). This point is important since co-immunoprecipitation studies determined that an ~50-kDa protein interacts with CPE soon after binding to Caco-2 cells (Wieckowski et al., 1994). The identity of that ~50-kDa protein is not yet clear, but those co-immunoprecipitation results could indicate 1) the ~50-kDa protein is the actual CPE receptor on natural CPE target cells, 2) there are multiple, independent CPE receptors on those cells, 3) the ~50-kDa protein is a claudin aggregate, or 4) claudins and the ~50-kDa protein serve together as co-receptors for CPE binding.

Upon binding to naturally sensitive cells, such as Caco-2 cells, CPE becomes localized in a small (~90-kDa) complex (Fig. 5). Formation of this small complex appears important for CPE action, as this CPE species is formed by all sensitive cells (Wieckowski et al., 1994). However, formation of the small complex is not sufficient for obtaining toxicity, as several CPE point mutants form the small complex, yet are nontoxic (Kokai-Kun et al., 1999). Furthermore, when native CPE is applied to sensitive cells at

Fig. 5. *Clostridium perfringens* enterotoxin (CPE) complex formation in rabbit intestinal brush border membranes (BBMs). Right panel: ^{125}I-CPE treatment of BBMs at 4°C in the presence (+) or absence (–) of excess unlabeled CPE. As unbound toxin was washed away, the BBMs were extracted with Triton X-100 and analyzed by nondenaturing gel electrophoresis. SC indicates migration of the small (90-kDa) CPE complex formed under this condition. Left panel: The same experiment as shown in the right panel, except ^{125}I-CPE treatment of BBMs was performed at room temperature (RT; not shown) or 37°C instead of 4°C. Note the presence of the additional higher M_r band that contains the larger CPE complexes (LC). If the BBMs treated at 4°C as in the right panel are washed and shifted to 37°C, some of the radioactivity present in the small complex now migrates with the larger complexes (not shown). For comparison, the migration of free CPE (no BBMs present) in this gel system is shown (CPE). From Wieckowski et al. (1994) with permission.

4°C, the bound toxin localizes only in the small complex, yet those CPE-treated cells remain unaffected (McClane and Wnek, 1990; Kokai-Kun et al., 1999).

If Caco-2 cells are treated with CPE at 4°C, washed to remove unbound CPE, and then shifted to 37°C, they rapidly develop cytotoxic responses (McClane and Wnek, 1990). Concurrently, with the onset of cytotoxicity in those cells, some bound CPE in small complex becomes localized in much larger plasma membrane complexes (Fig. 6). This finding indicates small complex formation is a precursor for formation of the larger CPE complexes and that those larger complexes are responsible for cytotoxicity. The involvement of the larger CPE-containing complexes in CPE cytotoxicity receives further support from 1) the identification of several nontoxic CPE point mutants that can bind and form the small complex but not the larger CPE complexes (Kokai-Kun et al., 1999), and 2) the identification (Kokai-Kun and McClane, 1997a) of several CPE deletion fragments that show, relative to native CPE, enhanced cytotoxic activity and better large complex-forming ability (see Structure/Function section).

The larger CPE complexes were recently resolved into two main species of ~155 kDa and ~200 kDa (Fig. 6). The TJ protein occludin is also present in the ~200-kDa complex (Fig. 6). A follow-up study (Singh et al., 2001) determined that 1) ~155-kDa CPE complex formation is sufficient for inducing cytotoxicity and 2) formation of the ~200-kDa complex removes occludin from TJs, with the TJ protein then internalized into the cytoplasm of Caco-2 cells. This occludin internalization effect, perhaps coupled with similar internalization of the claudins (another TJ component), could explain (McClane, 2000) CPE-induced damage to TJ structure and function (e.g., paracellular permeability alterations). This same study (Singh et al., 2001) also demonstrated the sensitivity of polarized Caco-2 cells to CPE-treatment of their apical surface, which is the cell surface initially exposed to CPE. Interestingly, Caco-2 cells were found to be even more sensitive when CPE is applied to their basolateral surface (Fig. 7).

Increasing evidence suggests that, when localized in the ~155-kDa complex, CPE forms pores that cause the plasma membrane permeability alterations responsible for cytotoxicity (Kokai-Kun and McClane, 1996; Wieckowski et al., 1998; Hardy et al., 1999). It is now clear that cell death pathways triggered by membrane permeability alterations are CPE dose-dependent (Chakrabarti et al., 2003). At low CPE concentrations, where plasma membrane permeability alterations develop more slowly, a classical caspase 3-mediated apoptosis develops. However, at

Kinetics of Large Complex Formation at 37°C

Fig. 6. Larger *Clostridium perfringens* enterotoxin (CPE) complex formation in CaCo-2 cells treated with CPE at 37°C. After the specified incubation times, CPE-treated cell suspensions were centrifuged, extracted with sodium dodecylsulfate (SDS), electrophoresed on 4% acrylamide gels containing SDS, and then Western immunoblotted with antibodies specific for either CPE (left panel) or occludin (right panel). Red and orange arrows show the migration of the ~200- and ~155-kDa CPE complexes, respectively. The green arrow shows migration of another CPE complex of ~135 kDa that is sometimes discernible in this experiment. From Singh et al. (2000) with permission.

higher CPE concentrations, more rapid development of membrane permeability changes occurs and caspase 3-independent oncosis is triggered.

CPE-induced enterocyte death via either apoptosis or oncosis produces histopathologic damage in vivo (McDonel, 1986). Tissue damage appears responsible for initiating intestinal fluid and electrolyte loss (McDonel, 1986; Sherman et al., 1994). CPE effects on paracellular permeability from TJ protein internalization may also contribute to intestinal fluid and electrolyte loss (McClane, 2000). Inflammation could also contribute to intestinal fluid and electrolyte losses, particularly when the high CPE doses that induce the proinflammatory process of oncosis are present (Chakrabarti et al., 2003).

CPE Structure/Function Relationships The 319-amino acid CPE polypeptide resembles many bacterial toxins by segregating its toxicity and binding domains (Fig. 8). Receptor binding activity resides in the extreme C-terminal portion of the enterotoxin (Hanna et al., 1989; Hanna et al., 1991; Hanna et al., 1992; Kokai-Kun and McClane, 1997a). Sequences necessary for toxicity are located in the N-terminal half of CPE (Kokai-Kun and McClane, 1996; Kokai-Kun and

McClane, 1997a); those sequences are required for formation of the ~155-kDa and ~200-kDa large complexes.

Interestingly, removing the first ~45 N-terminal amino acids from the native enterotoxin activates toxicity (Kokai-Kun and McClane, 1997a). This activation is not attributable to removal of a signal peptide, since CPE is not a secreted protein (Czeczulin et al., 1993). Intestinal proteases, such as trypsin and chymotrypsin, can activate the enterotoxin in vitro (Granum et al., 1981; Granum and Richardson, 1991), so similar proteolytic activation may occur in the intestines during GI disease.

A neutralizing linear epitope is present in the extreme C-terminal receptor-binding region of CPE (Hanna et al., 1992). A synthetic peptide corresponding to the C-terminal CPE sequences containing the neutralizing epitope induces formation of CPE-neutralizing antibodies (Mietzner et al., 1992). This observation supports the possible use of nontoxic C-terminal CPE sequences for development of a CPE vaccine.

CPE-associated Diseases CPE is important for the pathogenesis of *C. perfringens* type A food poisoning, CPE-associated nonfoodborne human GI diseases, and certain veterinary GI

CPE Cytotoxicity For Transwell Cultures of CaCo-2 and Vero Cells

CaCo-2 Cells   Vero Cells
Fig. 7. Cytotoxic effects of CPE on Transwella™ cultures of CaCo-2 cells and Vero cells. Cultures were radiolabeled with [86]RbCl for 2 h. After washing to remove unincorporated radiolabel, the cultures were treated with *Clostridium perfringens* enterotoxin (CPE), which was added (as indicated) to the top or bottom Transwella™ chamber. After 15 min incubation, culture supernatants were removed from each Transwella™ chamber and counted for radioactivity. The number of arrows shown corresponds to the relative level of ^{86}Rb release into that chamber. Note that Vero cells, which lack tight junctions, release radiolabel into both chambers. In contrast, CaCo-2 cells, which are polarized enterocyte-like cells forming tight junctions, release radiolabel only into the same chamber containing CPE. Also note that CaCo-2 cells are much more sensitive to CPE when treated on their basal surface. From McClane (2001b) with permission.

diseases (see Epidemiology and Disease sections for details).

Beta Toxin

Introduction Uncertainty regarding the biochemical properties (molecular mass, sequence, etc.) of *C. perfringens* β toxin was resolved when the gene (*cpb*) encoding this toxin was cloned and sequenced in the early 1990s (Hunter et al., 1993). These studies revealed that the *cpb* gene encodes a protein of 336 amino acids, including a 27-amino acid signal peptide. This processing leaves mature β toxin with a molecular mass of ~34.9 kDa.

Genetics Initial studies detected minor sequence differences between the *cpb* ORF sequence in a type B isolate vs. a type C isolate (Hunter et al., 1993; Steinsthorsdottir et al., 1995); whether
Fig. 8. *Clostridium perfringens* enterotoxin (CPE) structure/function relationship map. CPE regions important for the formation of large complexes/cytotoxicity and receptor binding are shown on this map.

these sequence differences hold true for other type B and C isolates is not yet clear. No studies have yet investigated the *cpb* promoter(s) or *cpb* regulation.

The *cpb* gene often, if not always, resides on large plasmids (Duncan et al., 1978), which have not yet received much study.

Mechanism of Action Beta toxin has lethal (LD_{50} via i.v. route = ~100 ng/mouse), dermonecrotic, and pressor activities (Leary and Titball, 1997).

Recent studies demonstrated that, reminiscent of CPE, β toxin forms at least two species of large complexes in sensitive HL60 cells (Nagahama et al., 2003). These complexes of ~191 kDa (presumably consisting of a β toxin hexamer) and ~228 kDa (presumably consisting of a β toxin heptamer) localize in lipid rafts. Formation of the ~228-kDa complex appears responsible for inducing membrane permeability alterations in HL60 cells. Whether similar membrane permeability effects are responsible for the in vivo effects of β toxin is not yet clear.

Structure/Function Relationships The amino acid sequence of β toxin shares 28% similarity with *Staphylococcus aureus* β toxin, which also alters plasma membrane permeability by forming heptameric complexes corresponding to plasma membrane pores (Hunter et al., 1993; Steinsthorsdottir et al., 1995).

The biologic activity of β toxin is susceptible to trypsin, helping to explain why people with diets rich in sweet potatoes, which contain a trypsin inhibitor, or suffering from pancreatic diseases are particularly susceptible to β toxin-mediated enteritis necroticans (Lawrence, 1997).

Associated Diseases Beta toxin contributes to the pathogenesis of necrotizing enteritis in humans, as well as veterinary necrotic enteritis and enterotoxemias (see Epidemiology and Disease sections).

Beta-2 Toxin

Introduction A 28-kDa toxic protein purified from type C strain CWC245 in the mid-1980s was originally identified as β toxin (Jolivet-Reynaud et al., 1986). However, subsequent cloning and sequencing studies indicated that the β toxin gene *cpb* actually encodes an ~34-kDa protein (Hunter et al., 1993; Steinsthorsdottir et al., 1995). This discrepancy was resolved in the mid-1990s when Popoff's group cloned and sequenced the gene encoding the 28-kDa protein produced by strain CWC245 (Gibert et al., 1997). These results unambiguously demonstrated that the 28-kDa protein is not β toxin but is instead a distinct new protein named β2 toxin.

Genetics The β2 toxin gene (*cpb2*) encodes a 265-amino acid protein, which includes an ~30-amino acid signal peptide for secretion (Gibert et al., 1997). The β2 toxin sequence shares no homology with β toxin or other known proteins.

The *cpb* 2 gene, which can be found in all *C. perfringens* types, resides on a large plasmid in most, if not all, isolates (Gibert et al., 1997). One *cpb2*-carrying plasmid, pCP13, has been sequenced; pCP13 does not encode any other toxins (Shimizu et al., 2002).

Studies are beginning to investigate the regulation of *cpb2* expression (Gibert et al., 1997; Ohtani et al., 2003). Promoter sequences reside immediately upstream of the *cpb2* start codon. A hairpin loop, which could be a ρ-independent transcriptional terminator, lies immediately downstream of the *cpb2* termination codon. The *cpb2* gene is maximally transcribed during the mid-exponential growth phase. Expression of β2 toxin is regulated via the VirR/VirS two-component regulatory system, which also regulates several other *C. perfringens* toxins (e.g., β toxin and perfringolysin O). VirR/VirS regulates expression of β2 toxin through a regulatory RNA named "VR-RNA."

Mechanism of Action Beta-2 toxin is lethal for mice (LD_{50} via i.v. route = ~3 μg/mouse) and cytotoxic for Chinese hamster ovary (CHO) and I407 cells (Gibert et al., 1997). It also has enterotoxic properties, causing fluid accumulation in guinea pig ileal loops, where it also induces substantial necrosis (Gibert et al., 1997). The molecular action of this toxin is not yet clear.

Structure/Function Relationships This issue has not yet been explored.

Associated Diseases Beta-2 toxin has been linked to several veterinary GI diseases, most notably porcine enteritis (see Epidemiology and Diseases sections for further details).

Epsilon Toxin

Introduction As discussed in the Epidemiology/Disease sections of this chapter, toxin has traditionally been viewed as only a veterinary concern. However, as the third most potent clostridial toxin (after botulinum and tetanus toxins), toxin is now a feared bioterrorism agent and thus listed as a class B select agent.

Genetics The gene (*etx*) encoding toxin produces, after removal of a 13-amino acid signal peptide during secretion, a 311-amino acid prototoxin (Hunter et al., 1992; Payne and Oyston, 1997). This prototoxin is relatively inactive until proteolytically processed (see Structure/Function Relationships, below). It has been suggested that promoter differences exist between the *etx*

genes of type B vs. D isolates (Hunter et al., 1992; Payne and Oyston, 1997), but this has not yet been proven.

In most or all type B and D isolates, the *etx* gene is present on large plasmids (Betancor et al., 1999). These plasmids have not yet been studied in detail, but in at least one type D isolate, the same plasmid can carry both the *etx* and *cpe* genes (Dupuy et al., 1997).

Mechanism of Action Epsilon toxin is highly lethal (LD_{50} via i.v. route = ~75 ng/mice), neurotoxic, enterotoxic, and cytotoxic (for Madin-Darby canine kidney [MDCK] cells). It can also induce intestinal histopathologic damage and edema in many organs (Payne and Oyston, 1997).

After being proteolytically activated in the gut, toxin affects the intestines, where it causes luminal fluid accumulation (Fernandez Miyakawa and Uzal, 2003). Epsilon toxin also induces histopathologic damage in the colon, which could assist the absorption of this toxin into the blood (Fernandez Miyakawa and Uzal, 2003). Once present in the blood, toxin circulates to all organs, resulting in numerous pathophysiologic effects, such as kidney necrosis, elevation of blood pressure, and increased vascular permeability (Payne and Oyston, 1997). The toxin also crosses the blood-brain barrier, where it causes edema and neuron damage that results in neurologic disorders, such as convulsions (see Diseases for more detail).

Molecular details of toxin action are now under intense study. Increasing evidence (Miyata et al., 2002; Petit et al., 2003) indicates that, at least in the sensitive MDCK cell culture model, toxin binds to an unidentified receptor and then forms a heptamer (Fig. 9). This toxin complex is present in lipid rafts and acts as a pore-like structure to alter plasma membrane permeability. Details of how this toxin effect on plasma membranes induces neurotoxicity, etc. remain unknown.

Structure/Function Relationships Studies (Miyata et al., 2001) have shown that the relatively inactive 311-amino acid prototoxin is converted to active toxin by either intestinal proteases (such as trypsin) or by *C. perfringens* proteases (such as λ toxin). These proteases remove 13 N-terminal and 22 C-terminal amino acids from the prototoxin; removal of the C-terminal amino acids is essential for heptamerization and thus (presumably) biologic activity.

Associated Diseases Epsilon toxin plays an important role in veterinary enterotoxemias caused by type B and D isolates of *C. perfringens* (see the Epidemiology and Diseases sections). As mentioned, the extreme potency of this toxin also makes it a bioterrorism concern, warranting its listing as a class B select agent.

IOTA TOXIN

Introduction Clostridium perfringens τ toxin is a member of the binary toxin family, which also includes *C. spiroforme* τ toxin, *C. difficile* CDT toxin, *C. botulinum* C2 toxin, and *B. anthracis*

Fig. 9. Formation of a large sodium dodecylsulfate (SDS)-resistant complex by recombinant ε-toxin species in synaptosomal membranes. ^{125}I-labeled recombinant ε-toxin species were bound to synaptosomal membranes, which were then washed and extracted with SDS. These SDS extracts were subjected to SDS-polyacrylamide gel electrophoresis (PAGE), followed by autoradiography. Lane 1, recombinant ε-prototoxin; lane 2, recombinant ε-prototoxin lacking 13 N-terminal amino acids naturally removable by proteases; lane 3, recombinant ε-prototoxin lacking 22 C-terminal amino acids naturally removable by proteases; lane 4, recombinant ε-toxin lacking both the 13 N-terminal and 22 C-terminal amino acids naturally removable by proteases. Note the heptamerization in lanes 3 and 4. These recombinant ε-toxin species in lanes 3 and 4 also had LD_{50} values nearly 100-fold lower than the species shown in lanes 1 and 2. From Miyata et al. (2001) with permission.

Type E Strain
Fig. 10. Organization of the plasmid-borne τ toxin gene locus in type E isolates. Note the presence of an IS*1151* sequence and a defective *cpe* gene immediately upstream of the *iap* and *ibp* genes. From Billington et al. (1998) with permission.

anthrax toxin (Carman et al., 1997b). These binary toxins all consist of binding and toxic polypeptides that only associate after the binding component becomes localized on the mammalian cell surface.

Genetics Iota toxin is encoded by two genes (Carman et al., 1997b). Both *iap* and *ibp* encode proteins with three domains: an N-terminal signal peptide, a propeptide, and the mature binding protein (see Structure/Function section for further description).

The *iap* and *ibp* genes are typically present together on the same large plasmid, where they lie in close proximity (Fig. 10). The close proximity of the *iap* and *ibp* genes allows them to form a bifunctional operon (Carman et al., 1997b). The transcriptional start site for *iap* lies ~135 bp upstream of the start codon. The *ibp* gene is also transcribed from the *iap* promoter, although inefficient transcription can occur from a promoter directly upstream of the *ibp* start codon.

Interestingly, the same plasmid carrying the *iap* and *ibp* genes typically has a defective *cpe* gene located immediately upstream of the τ toxin genes (Billington et al., 1998). It has been proposed that this plasmid resulted from the integration of a genetic element carrying the τ toxin gene near what was a functional, plasmid-borne *cpe* gene, with this insertion event inactivating the *cpe* promoter. Possible transfer of genetic elements carrying τ toxin genes is supported by the presence of binary toxin genes in several species of sporeforming bacteria. As type E isolates apparently share similar plasmids but lack chromosomal clonality, the plasmid carrying functional τ toxin genes and a defective *cpe* gene may have horizontally transferred between *C. perfringens* isolates.

Mechanism of Action Iota toxin has dermonecrotic, lethal (LD_{50} via i.v. route = ~100 ng/mouse), cytotoxic, and enterotoxic properties (Carman et al., 1997b). The toxin can also induce intestinal histopathologic damage.

The molecular action of τ toxin involves proteolytic removal of a propeptide from both τ a and τ b (Gibert et al., 2000). The activated τ b binds to still unidentified protein receptors on mammalian cells (Carman et al., 1997b). The activated τ a component then binds to the cell-associated τ b component. The resultant toxin complex is internalized via endocytosis. The τ b component then probably mediates entrance of the τ a component into the cytoplasm, where it ADP-ribosylates actin at the Arg-177 residue. How that effect translates into intestinal pathology is not yet clear.

Structure/Function Relationships Iota toxin has become very well-studied at the structural level (Sakurai et al., 2003). As mentioned, it now appears that the τ a component must be proteolytically activated (Gibert et al., 2000). This can be achieved by either *C. perfringens* λ toxin or chymotrypsin, which removes 9–13 amino acids from the N-terminus of the τ a prototoxin. Sequence comparisons indicated that the mature τ a component contains all three conserved regions of classical ADP-ribosylating bacterial toxins 1) the aromatic residue-arginine/histidine (R/H) motif involved in nicotinamide adenine dinucleotide (NAD) binding, which includes Phe-349 and Arg-295/296 of τ a, 2) the hydrophobic residue-serine-threonine-serine (S-T-S) sequence that forms the floor of the catalytic cavity, which includes Ser-338, Ser-340 and Thr-339 of τ a, and 3) the glutamate-aspartate-glutamate (E-X-E) motif extending towards the catalytic cavity, which involves Glu-378 and Glu-380 of τ a. Site-directed mutagenesis studies have now confirmed the importance of most of these amino acid residues for the ADP-ribosylating activity of τ a (Sakurai et al., 2003). The crystal structure of τ a complexed with nicotinamide adenine dinucleotide phosphate (NADPH) was recently solved at 1.8Å resolution (Fig. 11). This structure indicates τ a is a two-domain protein consisting of a N-terminal domain (amino acids 1–210) and a C-terminal domain (amino acids 211–413). Both domains have a β-sandwich core surrounded by α helices. NADH or NADPH binds to a cavity located in the C-terminal domain. The aromatic residue-R/H, S-T-S and E-X-E regions important for ADP-ribosylating activity are also present in a cavity present in the C-terminal domain.
Fig. 11. Structure of the τ a component of τ toxin. Secondary structure elements are shown in red (α helices), light blue (β strands) and gray (loops). Note the location of the NADH binding site in the C-domain. From Sakurai et al. (2003) with permission.

Studies of the τ b component indicate that the 39 N-terminal amino acids encoded by the *ibp* ORF are a signal peptide that is removed during secretion (Carman et al., 1997b). The resultant prototoxin includes a 171 propeptide that is then removed by bacterial and intestinal proteases to form the mature τ b binding component of 664-amino acid residues.

Associated Diseases Iota toxin has been linked to several veterinary GI diseases caused by type E isolates of *C. perfringens* (see Diseases and Epidemiology sections).

Epidemiology: *C. perfringens* Gastrointestinal Diseases of Humans

CLOSTRIDIUM PERFRINGENS TYPE A FOOD POISONING CPE-positive *C. perfringens* type A isolates are the second and third most common cause of foodborne disease in the United Kingdom and United States, respectively (Bean et al., 1996; Adak et al., 2002). Recent, likely conservative, United States Centers for Disease Control and Prevention (CDC) estimates indicate that ~250,000 cases of this illness occur annually in the United States (Mead et al., 1999). *Clostridium perfringens* type A food poisoning is often mild, but can result in fatalities, particularly in the elderly or debilitated persons. For example, this food poisoning kills ~7 persons/year in the United States (Mead et al., 1999) and ~50–100 persons/year in the United Kingdom (Adak et al., 2002).

Two unusual epidemiologic features of *C. perfringens* type A food poisoning outbreaks are their unusually large size and their association with institutionalized settings (McClane, 2001a).

These epidemiologic patterns are probably attributable to two factors: 1) institutions often prepare foods in advance and then must hold that food for later serving, allowing the rapid growth of *C. perfringens* in any temperature-abused food (recall that the doubling time of this bacterium can be as little as ~10 min), and 2) public health officials usually confirm the identity of *C. perfringens* type A food poisoning cases only when large numbers of people become ill in a single outbreak.

The most commonly involved food vehicles in *C. perfringens* type A food poisoning outbreaks are meats and poultry (McClane, 2001a). Stews, gravies and Mexican foods are also important for transmission of this illness. Temperature abuse during storage or holding of foods is a contributing factor to nearly 100% of all *C. perfringens* type A food poisoning outbreaks, while incomplete cooking of foods or use of contaminated food preparation equipment are involved in ~30% and 15%, respectively, of all outbreaks of this disease. The importance of temperature abuse during cooking and holding of foods in the development of *C. perfringens* type A food poisoning is not surprising given the exceptional heat resistance noted for spores and vegetative cells of food poisoning isolates (Sarker et al., 2000).

The best way to reduce the frequency of *C. perfringens* type A food poisoning outbreaks is, first, to thoroughly cook foods. This is particularly true of the large roasts and turkeys that are often vehicles for this food poisoning and where it is more difficult to reach the high internal temperatures necessary to kill *C. perfringens* cells and spores. After cooking, it is then essential to cool foods rapidly and then store those foods under nonpermissive growth conditions for *C. perfringens*, e.g., at 4°C.

CPE expression appears to be both required and sufficient for the pathogenesis of *C. perfringens* type A food poisoning. Specific inactivation of the *cpe* gene eliminates the ability of a human food poisoning isolate to cause histopathologic damage or fluid accumulation in rabbit ileal loops (Fig. 12). Enteric virulence can be fully restored by complementing that *cpe* knock-out mutant with a wild-type *cpe* gene (Fig. 12), i.e., this human food poisoning isolate must express CPE to cause intestinal effects in this animal model. Additionally, human volunteer feeding studies conducted in the 1970s demonstrated that ingestion of purified CPE is sufficient to reproduce the cramping and diarrheic symptoms of this food poisoning (Skjelkvale and Uemura, 1977).

CPE-ASSOCIATED NONFOODBORNE GI DISEASES The epidemiology of CPE-associated nonfood-

Histologic Damage Induced By CPE-Positive
Clostridium perfringens Strain SM101

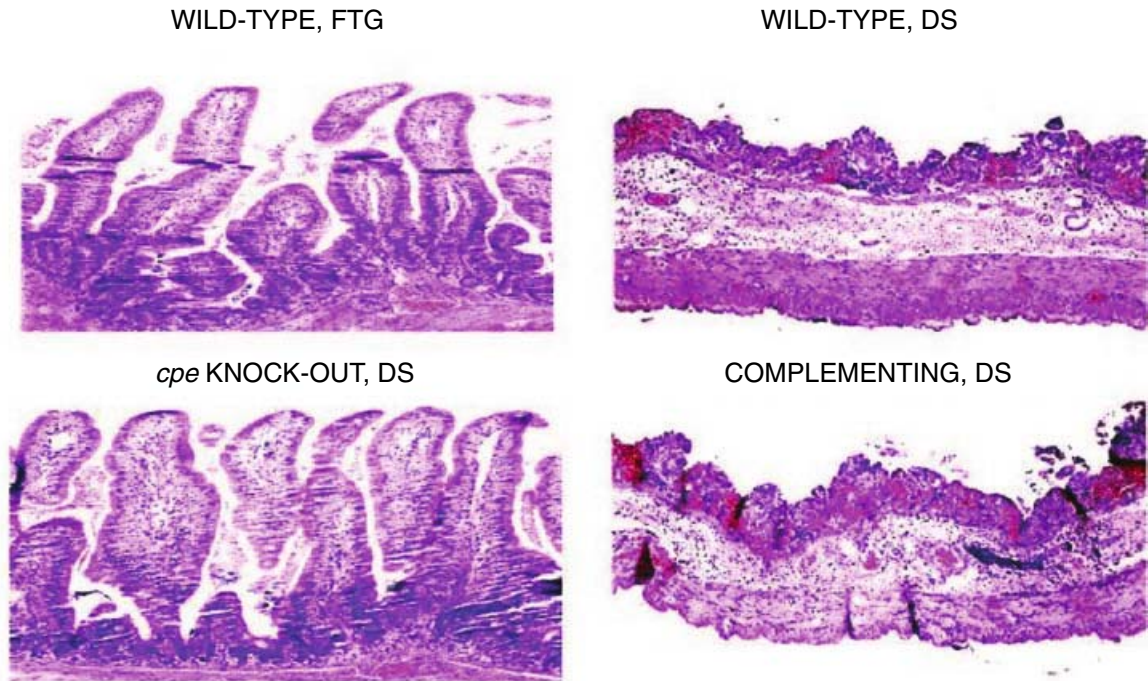
cpe KNOCK-OUT, DS   COMPLEMENTING, DS


Fig. 12. Histopathologic damage induced by culture lysates of *C. perfringens* type A food poisoning isolate SM101 and derivatives. Tissue specimens shown were collected from rabbit ileal loops treated with either concentrated lysates from vegetative (fluid thioglycolate [FTG] medium) or sporulating (Duncan and Strong [DS] medium) cultures of wild-type *C. perfringens* isolate SM101 (a CPE-positive, transformable strain derived from food poisoning isolate NCTC8798; Zhao and Melville, 1998), the isogenic *cpe* knock-out mutant MRS101, or the *cpe*-complementing strain MRS101(pJRC200). Note extensive epithelial desquamation and severe villi shortening are present in loop samples treated with DS lysates of SM101 or MRS101 (pJRC200) but not in loops treated with FTG lysates of SM101 or DS lysates of MRS101. Similarly, no tissue damage was apparent (not shown) in loops treated with concentrated FTG lysates of MRS101 or MRS101(pJRC200). Ileal loop fluid accumulation was only present in those loop samples showing histopathologic damage. From Sarker et al. (1999) with permission.

borne GI diseases is still incompletely understood. Some evidence suggests these illnesses result from ingestion or inhalation of environmental *C. perfringens* isolates (Borriello et al., 1985c). These illnesses are more prevalent in the elderly and in people taking antibiotics. They can often occur in nosocomial settings, where they may be transmitted person-to-person.

ENTERITIS NECROTICANS Type C isolates of *C. perfringens* cause enteritis necroticans, a potentially lethal human enteric infection (Johnson and Gerding, 1997; Lawrence, 1997). This illness was first noted in malnourished Germans at the end of World War II, where it was named "darmbrand" ("fire bowels"). The most thorough epidemiologic studies of enteritis necroticans to date have been conducted in the

highlands of Papua New Guinea (PNG), where this illness is known as "PigBel." This illness is also endemic in other developing areas of Southeast Asia. Enteritis necroticans from type *C. perfringens* occasionally occurs in developed countries, where it often involves people with pancreatic or intestinal disease.

In PNG, about 70% of PigBel cases occur in children, with a peak incidence in 4-year-olds. Infants do not typically become ill with PigBel, perhaps because of maternal immunity. Interestingly, the peak ages affected by darmbrand were infants and the elderly.

As described in the Clinical Illness section of this chapter, sanitation, malnourishment and/or underlying pancreatic and intestinal disease play important contributing roles in the development of enteritis necroticans.

In 1980, a vaccine utilizing a β toxoid preparation was introduced in the PNG highlands, where it reduced hospital admissions for PigBel by ~80% (Johnson and Gerding, 1997; Lawrence, 1997). This finding supports the importance of β toxin in the pathogenesis of this illness.

Epidemiology: *C. perfringens* Veterinary Enterotoxemias

Besides its broad distribution in the environment, particularly in soil, *C. perfringens* is very frequently found in the digestive tract of clinically healthy animals (Bullen, 1952; Niilo, 1980; Van Baelen and Devriese, 1987; Tschirdewahn et al., 1991; Ardehali et al., 1994). Most intestinal diseases produced by *C. perfringens* in animals are generically called "enterotoxemias," a term that implies production of toxins in the gastrointestinal tract and absorption into the general circulation with systemic effects. This is true for some of the intestinal infections by *C. perfringens* (for example *C. perfringens* type D infection in sheep) but not for other *C. perfringens* infections, in which most damage is caused by a toxin (or toxins) that is produced, and remains, in the intestines (for instance, *C. perfringens* type D enterotoxemia in adult goats). As a general rule, clostridial veterinary enterotoxemias have a low incidence but a high mortality.

Clostridium perfringens Type A *Clostridium perfringens* type A is the most ubiquitous of the *C. perfringens*; it is found in most soils and is also highly prevalent in the intestine of most warm-blooded animals (Itodo et al., 1986; Songer, 1996; Uzal and Marcellino, 2002a). In different surveys of the types of *C. perfringens* present in the intestine of healthy ruminants and soil, *C. perfringens* type A was found in 51–86.6% of the samples examined (Itodo et al., 1986; Uzal and Marcellino, 2002a). Because *C. perfringens* type A is highly prevalent in the intestines of healthy animals, controversy exists about its real pathogenic role.

An exception to this uncertainty, however, is with chickens, where there is considerable evidence that *C. perfringens* type A is responsible for necrotic enteritis. In this species, damage to the intestinal mucosa by high fiber diets or concurrent infection by coccidia are the most likely predisposing factors for necrotic enteritis (Nairn and Bamford, 1967; Helmboldt and Bryant, 1971; Al-Sheikhly and Al-Saieg, 1980; Shane et al., 1985; El-Seedy, 1990; Songer, 1996). It has also been demonstrated that germ-free chickens have higher mortality than conventional chickens (Fukata et al., 1988; Fukata et al., 1991), which suggests that the normal intestinal flora

plays a role in the pathogenesis of this disease. Cholangiohepatitis in chickens is also believed to be produced by *C. perfringens* type A. While it has been assumed that the risk factors for this disease are the same as those for necrotic enteritis, this has not been confirmed (Onderka et al., 1990).

Clostridium Perfringens Types B and C Type B produces diseases in several animal species and can be found, although infrequently, in the intestine of healthy animals (Onderka et al., 1990; Uzal and Marcellino, 2002a). This type of *C. perfringens* has been found in 4.25–7.1% of healthy ruminants in different surveys (Itodo et al., 1986; Uzal and Marcellino, 2002a). For reasons that are not very clear, disease caused by *C. perfringens* type B has been reported only in a few regions of the world. This type of *C. perfringens* affects mainly sheep, and disease in this species has been reported in the United Kingdom, South Africa, the Middle East (Timoney et al., 1988) and the United States (Tunnicliff, 1933). However, *C. perfringens* type B has also been isolated from intestinal contents of healthy animals in countries or regions where disease has not been reported (Uzal and Marcellino, 2002a). Although it is possible that the lack of reported diagnosis in some regions or countries of the world is due to diagnostic difficulties, it would also appear that other factors, in addition to the presence of the microorganism, are necessary for disease to occur.

Type C has been isolated from a great variety of species associated or not with clinical disease (Timoney et al., 1988; Songer, 1996). In surveys of healthy ruminants, this microorganism was isolated from the intestinal content of 4.9% of the samples in one study (Itodo et al., 1986), while no *C. perfringens* type C was isolated in another (Uzal and Marcellino, 2002a). Infections by *C. perfringens* type C have been reported in sheep, cattle, pigs, horses, chickens, dogs and humans in several countries (Mackinnon, 1989; Songer, 1996).

The main pathogenic factor of *C. perfringens* types B and C is β toxin (Table 2). Beta toxin is very sensitive to the action of trypsin, and newborn animals are usually the most susceptible to infection by these microorganisms, since little protease activity is present in the gut of these animals (Barker et al., 1993). Also, it has been suggested that newborn animals are more often infected by *C. perfringens* types B and C because of the ready colonization of the gut by *C. perfringens* in the absence of well established normal intestinal flora (Songer, 1996). As with the other *C. perfringens* types, dietary changes may also be a predisposing factor in infections by *C. perfringens* types B and C (Timoney et al., 1988).

CLOSTRIDIUM PERFRINGENS TYPE D Disease from *C. perfringens* type D has been reported in several species, but it is most prevalent in sheep and goats. Despite the common belief that this microorganism is a normal inhabitant of the intestine of most ruminants, different surveys isolated *C. perfringens* type D from less than 20% of the animals, and there were farms where it was not isolated at all (Itodo et al., 1986; Uzal and Marcellino, 2002a).

In sheep, enterotoxemia by *C. perfringens* type D has been reported in most sheep producing areas of the world (Carrillo et al., 1982; Lewis, 2000). The disease seems to be more prevalent in animals 3 weeks to 10 months old (Blood et al., 1983), but it can occur throughout the entire life of the animals. In this species, most enterotoxemia cases occur soon (a few hours to a few days) after sudden changes in diet, usually to diets rich in highly fermentable carbohydrates (Bullen, 1952; Lewis, 1998; Lewis, 2000), which promote the overgrowth of *C. perfringens* type D present in the intestine of healthy animals. Examples of this are the introduction of animals to feedlots without progressive adaptation to grains or concentrated rations, and access to lush grass after rains in spring and autumn. Overeating also appears to play an important role in the pathogenesis of enterotoxemia (Bullen, 1963). Because of these predisposing factors, fat, well-fed animals are particularly susceptible (Blood et al., 1983). Other factors that disturb the intestinal environment have also been suggested as predisposing factors for enterotoxemia in sheep, although no final proof of this has been reported. Among these is heavy tape-worm infestation (Thomas et al., 1956; Elliot, 1986) and dosing with phenothiazine (Jansen, 1960).

Morbidity rates can vary but seldom exceed 10% (Blood et al., 1983). The disease is almost 100% lethal (Hartley, 1956; Blood et al., 1983; Lewis, 2000).

Caprine enterotoxemia by *C. perfringens* type D occurs worldwide in goats of any age older than two weeks (Baxendell, 1988). The factors predisposing goats to enterotoxemia by *C. perfringens* type D have not been well defined, although it is usually assumed that, as in the case of sheep, any factor that increases the amount of starch in the small intestine could predispose goats to the disease. Factors such as sudden changes from poor to lush pasture, feeding of bread or other bakery goods, feeding of a bran/molasses mash, excessive concentrates consumption and feeding of garden greens to goats unaccustomed to green feed have been reported (King, 1980).

In addition to the dietary factors, other prerequisites seem to be necessary for the development of enterotoxemia in goats. For instance, Smith and Sherman (1994) reported an outbreak of enterotoxemia in a herd of goats that had been fed a consistent diet of hay and concentrates for many months before the outbreak. In cases like this, it is possible that errors in the mixing of the rations may have been responsible for an overdose of grain in some goats. Also, some outbreaks of enterotoxemia type D have been reported to occur in goats under extensive grazing systems without known diet change (Van Tonder, 1975; Uzal et al., 1994). An accidental overdose of an antihelmintic, cold weather stress, and a concomitant infestation with coccidia were suggested as possible predisposing factors in one outbreak of caprine enterotoxemia (Uzal et al., 1994). Heavy worm burden has also been reported as a predisposing factor for enterotoxemia in goats (King, 1980).

Individual sporadic cases or outbreaks of enterotoxemia with high morbidity have been observed (Smith and Sherman, 1994; Uzal et al., 1994). The persistence of *C. perfringens* type D in the environment, derived from previous cases of enterotoxemia, or from constant fecal contamination from animals in which this microorganism is part of the normal intestinal flora, could be an explanation for this disease pattern, although sudden changes in diet, as in the case of sheep, are most likely to be the major predisposing factors (Smith and Sherman, 1994). Although *C. perfringens* type D is usually considered to be a normal inhabitant of the alimentary tract of goats (Bullen, 1952; Niilo, 1980), there have only been a few documented reports of the isolation of *C. perfringens* type D from the intestinal tract or feces of healthy goats (Sinha and Kuppuswamy, 1969; Sinha, 1970).

Despite a generalized belief among producers and veterinarians that many unexplained sudden deaths in cattle are due to type D enterotoxemia (Blood et al., 1983), laboratory evidence does not seem to support such field observations, and there are only a few reports (Munday et al., 1976) about this condition in cattle. Epidemiological information about type D enterotoxemia is therefore almost nonexistent, although it is commonly assumed that the same factors that predispose sheep and goats to *C. perfringens* type D enterotoxemia, are predisposing factors for the disease in cattle (Barker et al., 1993).

CLOSTRIDIUM PERFRINGENS TYPE E Information about the prevalence of *C. perfringens* type E in the environment and in the intestine of healthy animals is scant. In a survey of this microorganism in the intestine of sheep, cattle and soil in Nigeria, *C. perfringens* type E was isolated from 7.9% of the samples (Itodo et al., 1986).

With the exception of the rabbit, epidemiological information about *C. perfringens* type E infection in animals is almost nonexistent. Although for many years, *C. perfringens* type E was regarded as the etiological agent of rabbit enterotoxemia, it is possible that many of those cases may have been due to *C. spiriforme*, since antitoxin prepared against *C. perfringens* type E τ toxin will also neutralize similar toxins produced by *C. spiriforme* (Songer, 1996; Percy and Barthold, 2001). The pathogenesis of this disease is believed to be similar to the carbohydrate overload model explained for sheep and goats; rabbits ingesting high energy feed may fail to degrade and digest the majority of carbohydrates in the small intestine. The majority of carbohydrates may then reach the large intestine promoting the overgrowth of *C. perfringens* (Percy and Barthold, 2001).

Clinical Illness: *C. perfringens* Gastrointestinal Diseases of Humans

CLOSTRIDIUM PERFRINGENS TYPE A FOOD POISONING

Disease As illustrated in Fig. 13, this food poisoning typically develops after ingestion of foods that are grossly contaminated (~10^6 bacteria/gram of food) with vegetative cells of a *C. perfringens* type A isolate carrying a chromosomal *cpe* gene (McClane, 2001a). Many ingested vegetative cells are killed by the acidity of the stomach, but when sufficient numbers of vegetative cells are ingested, some survive and pass into the small intestines. After initially multiplying in the intestines, these bacteria soon commit to sporulation. The trigger for this in vivo sporulation may involve (McClane, 2001a) an acid-shock response (in the stomach) and/or a response to bile exposure (in the intestines).

It is during sporulation in the intestines that *C. perfringens* expresses the enterotoxin, which then accumulates in the cytoplasm of the mother cell (McClane, 2001a). Therefore, CPE is not a secreted protein but instead is released into the intestinal lumen at the conclusion of sporulation as the mother cell lyses to release its mature spore. The enterotoxin then binds and exerts its molecular action (described in the Toxins section of this chapter) to kill enterocytes via apoptosis and/or oncosis, depending on CPE dosage. This cytotoxic effect produces histopathologic damage that begins at the villus tip and progresses to include severe epithelial desquamation and villus shortening. CPE-induced intestinal histopathologic damage can appear within 30 min of toxin treatment and appears responsible for initiating intestinal fluid and electrolyte losses (Sherman et al., 1994). With time, CPE-induced paracellular permeability effects and/or inflammation (see the Toxins section) may also contribute to intestinal electrolyte and fluid losses.

In rabbit models, CPE is active on all segments of the small intestine, with the ileum being particularly sensitive (McDonel, 1986). In this animal model, CPE does not affect the large intestine; however, it remains unclear whether the human colon is CPE-sensitive.

Common symptoms of *C. perfringens* type A food poisoning include diarrhea and abdominal cramps (McClane, 2001a). These symptoms usually begin about 12 h after ingestion and then persist for 12–24 h. In most cases a victim makes a full recovery, although this food poisoning can be fatal (see the Epidemiology section). Expo-

Clostridium perfringens Food Poisoning

Fig. 13. The pathogenesis of *C. perfringens* type A food poisoning. A food item (usually a meat or poultry item) becomes contaminated with vegetative cells of a type A isolate carrying a chromosomal *Clostridium perfringens* enterotoxin (*cpe*) gene. After ingestion, those bacteria sporulate in the intestines. During that in vivo sporulation, CPE is produced. The toxin is then released into the lumen at the completion of sporulation (when the mother cell lyses). Once free, the enterotoxin binds and, via membrane permeability alterations, kills enterocytes, producing intestinal damage that initiates diarrhea and cramping. From McClane (1992) with permission.
sure to *C. perfringens* type A food poisoning induces an immune response against the enterotoxin, but there is no evidence that previous exposure provides immunity.

Diagnosis Public health officials first use epidemiologic criteria (incubation time, symptoms, etc.) to evaluate the possible involvement of *C. perfringens* in a food poisoning outbreak (McClane, 2001a). However, given that the epidemiologic characteristics of *C. perfringens* type A food poisoning and the diarrheal form of *Bacillus cereus* food poisoning are indistinguishable, laboratory analyses often prove pivotal for diagnosis. Quantitative bacteriologic analysis of feces were traditionally used to identify a *C. perfringens* type A food poisoning outbreak, but that approach is imprecise, i.e., many healthy people, particularly the elderly, carry large numbers of (*cpe*-negative) *C. perfringens* isolates in their feces (McClane, 2001a). Both the CDC and United States Food and Drug Administration (FDA) now also use fecal CPE detection from two or more food poisoning victims as a diagnostic criterion for identifying a *C. perfringen*s type A food poisoning outbreak. Several commercial serologic CPE detection assays (enzyme-linked immunosorbent assays [ELISAs] and restriction fragment length polymorphism [RFLP] assays) are available for this purpose. It should be emphasized that CPE detection works best when fecal samples are collected soon after the onset of illness; with time, fecal CPE levels fall markedly and are more difficult to detect (McClane, 2001a).
Fig. 14. Duplex polymerase chain reaction (PCR) *Clostridium perfringens* enterotoxin gene (*cpe*) genotyping assay. Results obtained using purified DNA extracted from type A isolates carrying a chromosomal *cpe* locus (lanes 2–6 from left) or plasmid *cpe* locus (next 13 lanes). Also shown are negative results using *cpe*-negative type A isolate 297442 (far right lane). Arrows at right depict migration of ~3.3-kb PCR product from chromosomal *cpe* locus or ~2.1-kb PCR product from plasmid *cpe* locus of type A isolates. Numbers at left indicate the migration of molecular size markers. From Wen et al. (2003) with permission.

For epidemiologic investigations, it can also be useful to demonstrate the presence of *cpe*-positive *C. perfringens* isolates in foods or feces associated with a food poisoning outbreak. For this purpose, a multiplex polymerase chain reaction (PCR) assay is available (Garmory et al., 2000). A *cpe* genotyping PCR can then be used to specifically determine whether those food or fecal isolates carry the chromosomal *cpe* gene that is strongly associated with food poisoning (Fig. 14).

Treatment No specific treatment is used for cases of *C. perfringens* type A food poisoning. As for all diarrheal diseases, supportive fluid and electrolyte restoration is important.

CPE-Associated Nonfoodborne Human GI Diseases

Disease Clostridium perfringens type A strains carrying a *cpe* plasmid cause several nonfoodborne human GI diseases (Carman, 1997a), including antibiotic-associated diarrhea (AAD) and sporadic diarrhea (SD). Some evidence suggests CPE-associated AAD/SD, which often occur in institutions such as hospitals or nursing homes, result from person-to-person transmission or ingestion of environmental contaminants (Borriello et al., 1985c). However, the possibility that these diseases also result from antibiotic-induced overgrowth of normal flora cannot yet be ruled out.

Estimates vary considerably between surveys, but CPE-associated AAD and SD apparently causes from 1% up to 5–20% of all cases of these human GI illnesses (Carman, 1997a). The pathogenesis of CPE-associated AAD and SD remains poorly understood, but their symptoms include diarrhea and cramping (Borriello et al., 1984; Borriello, 1995). These symptoms are often more severe and longer lasting (up to several weeks) than the typical GI symptoms of *C. perfringens* type A food poisoning. These differences could result from transfer of the *cpe* plasmid from the few infecting *cpe*-positive strains initiating AAD and SD to the many *cpe*-negative *C. perfringens* isolates present in the normal intestinal flora (Brynestad et al., 2001). As those normal flora isolates are presumably under selection for colonization, this putative in vivo virulence conversion via *cpe* plasmid transfer could produce fully pathogenic isolates with enhanced colonization ability.

CPE-associated AAD and SD are most common in the elderly (Borriello et al., 1984; Carman, 1997a). The extent of fatalities from these infections is not clear at present.

Diagnosis Most cases of CPE-associated AAD/SD are initially identified by fecal CPE detec-

tion. Therefore, it becomes important to distinguish whether a case involves food poisoning or AAD and SD, e.g., can a contaminated food source be identified? Genotyping of isolates (Fig. 14) to determine if they carry the plasmid *cpe* gene typically associated with AAD and SD is also helpful, but not foolproof, as an atypical food poisoning outbreak involving plasmid *cpe* isolates was recently identified in Japan (Tanaka et al., 2003).

Treatment In most cases of CPE-associated AAD/SD, only symptomatic therapy to restore fluid/electrolyte balance is necessary. For severe cases, metronidazole has been successfully used (Borriello et al., 1984; Borriello, 1985a; Borriello et al., 1985c; Borriello, 1995).

Enteritis Necroticans

Disease The pathogenesis of PigBel is now fairly well understood (Lawrence, 1997). People in the PNG highlands eat a diet rich in sweet potatoes, which contain a potent trypsin inhibitor. This low protein diet also reduces their production of pancreatic proteases, including trypsin. These predisposing factors become important on special occasions when in PNG typically a pig is killed and cooked (often under unsanitary conditions) for consumption by the celebrants. A pork vehicle is an important contributing factor for the development of PigBel as *C. perfringens* type C isolates are often present in pigs. In incompletely cooked foods, these bacteria survive and, once ingested, multiply and produce β toxin in vivo. Normally this toxin would simply be inactivated by intestinal trypsin, but in the PNG highlands population, this does not occur owing to the presence of trypsin inhibitor (from sweet potatoes) and low trypsin levels (from a protein-poor diet) present in that population. Consequently, β toxin remains active in the intestines, where it induces intestinal necrosis. The question remains whether β toxin is the only toxin involved in the pathogenesis of enteritis necroticans caused by type C isolates, since purified β toxin alone does not induce substantial intestinal damage.

In developed countries, most cases of enteritis necroticans occur in people with pancreatic diseases affecting production of trypsin (Johnson and Gerding, 1997). Poor diet and/or low intestinal motility can also be contributing factors.

The primary symptom of enteritis necroticans is abdominal pain (Johnson and Gerding, 1997). In PNG, this pain typically develops ~1–5 days after eating the protein-rich meal (i.e., pork); the most severe cases develop very quickly after eating the contaminated food product. There may also be vomiting and bloody diarrhea. In severe cases of the disease, intestinal obstruction due to necrosis of the small bowel (particularly the jejunum) develops. Affected intestinal tissue shows necrosis and hemorrhaging, with polymorphonuclear leukocyte (PMN) infiltration.

Death can occur from toxemia (Johnson and Gerding, 1997). Some cases are so rapidly fatal that the individual never makes it to the hospital. Prior to the introduction of a β toxoid vaccine in 1980, PigBel ranked as the second leading cause of death in PNG children after weaning.

Diagnosis Enteritis necroticans is diagnosed solely on the basis of clinical signs (Johnson and Gerding, 1997). The abdomen is typically distended and thickened loops of bowel are often palpable on examination.

Treatment Management of enteritis necroticans involves a combination of nasogastric suction, intravenous fluids, antimicrobial therapy and, frequently, surgical resection of the affected bowel segment (Johnson and Gerding, 1997). A number of antimicrobials have been used, including penicillin, chloramphenicol and metronidazole. The most important factor for successful management of this disease is the timing of surgery. Patients are usually observed for 1–2 days; if there is no improvement, laparotomy is performed (this surgical procedure can be performed even earlier for severe cases). Delaying surgery can have a negative outcome.

Clinical Illness: *C. perfringens* Veterinary Enterotoxemias

Disease Veterinary enterotoxemias caused by *C. perfringens* are the consequence of the local or systemic action of the toxins produced by this microorganism in the gastrointestinal tract. The main features of the most important enterotoxemias produced by each *C. perfringens* type in the most relevant domestic animal species are discussed here.

Clostridium perfringens type A

Sheep *Clostridium perfringens* type A produces a rare form of enterotoxemia in lambs that has been described in California and Oregon in the United States (McGowan et al., 1958). This condition, also known as "yellow lamb disease" (McGowan et al., 1958), is characterized clinically by depression, anemia, icterus, hemoglobinuria and acute death (McGowan et al., 1958; Songer, 1996). Postmortem changes consist of generalized icterus (Fig. 15) and enlarged, pale and friable livers. Red tinged urine is found in the urinary bladder (McGowan et al., 1958).

Fig. 15. Yellow lamb disease by *Clostridium perfringens* type A. Diffuse icterus.

Fig. 16. Hemorrhagic bowel syndrome. Serosal view (A) and cross-section of small intestine (B). Photograph courtesy of Deryck Read.

Fig. 17. Hemorrhagic colitis in a horse (colitis X). The role of *C. perfringens* in this condition has not been proven. Photograph courtesy of Roger Kelly.

Goats A condition clinically similar to yellow lamb disease has been reported (Russell, 1970), but definitive confirmation of the role of this microorganism in disease production has not been reported (Barron, 1942; Russell, 1970; Guss, 1977; Songer, 1998).

Cattle Though producers, veterinarians and vaccine producers claim *C. perfringens* type A is important in diseases of cattle (Manteca et al., 2002; F. A. Uzal, unpublished observations), this microorganism's role in disease production in this animal has not been firmly established (Songer, 1996; Petit et al., 1999). *Clostridium perfringens* type A has been isolated in the western United States from calves with tympany, diarrhea and high mortality (Songer, 1996). At postmortem examination, hemorrhage and ulceration of the abomasal mucosa, necrohemorrhagic enteritis of the jejunum, ileum and sometimes colon are the most striking gross changes (Songer, 1996). Although *C. perfringens* isolates originating from cases of enteritis in cattle were highly enterotoxigenic type A strains (Niilo, 1978), Koch's postulates have not been fulfilled (Songer, 1996), and the role of *C. perfringens* type A in disease of cattle is not yet defined. It has also been suggested that *C. perfringens* type A is involved in the pathogenesis of a condition in cattle called "hemorrhagic bowel syndrome" (Denison et al., 2002; Fig. 16), but to date no evidence has been provided to confirm this hypothesis. Further research is necessary to clarify the roles of different predisposing factors, this microorganism, and its toxins in disease pathogenesis in cattle.

Horses *Clostridium perfringens* type A has been suggested to be the etiological agent of a condition of horses called "colitis X," characterized by watery or bloody diarrhea and hemorrhagic colitis (Barker et al., 1993; Fig. 17). Large numbers of *C. perfringens* type A have been found in the gut of these animals, although a definitive role of this microorganism in colitis X has not been proved (Songer, 1996). The action of other bacteria (such as *Salmonella* sp.) as primary patho-

gens and proliferation of *C. perfringens* as a result of disruption of the bacterial ecosystem in the colon has been hypothesized for this condition (Barker et al., 1993).
Chickens *Clostridium perfringens* type A produces necrotic enteritis in chickens (Long and Truscott, 1976; Niilo, 1978; Baba et al., 1992). Under appropriate conditions (high fiber diets, concurrent coccidia infection, and reduced intestinal flora), the organism replicates readily in the intestinal tract, where it produces the α toxin believed to be responsible for the clinical signs and pathological changes of the disease (Ficken et al., 1997). The disease usually takes an acute course, although subclinical disease that does not result in mortality but is associated with poor performance can also be observed (Prescott, 1979; Kaldhusdal and Hofshagen, 1992). Postmortem lesions consist of dilated small intestine (jejunum and ileum) with dark brown granular content (Fig. 18), mucosal necrosis (Nabuurs et al., 1983; Ratz et al., 1989), and catarrhal colitis (Ratz et al., 1989) with a large number of Gram-positive rods observed. Alpha toxin's role in this disease is supported by observations that duodenal infusion or oral inoculation of chickens with preparations of this toxin can reproduce the lesions of intestinal necrosis (Al-Sheikhly and Truscott, 1977; Fukata et al., 1991).

Clostridium perfringens type A has also reportedly produced cholangiohepatitis in chickens (Onderka et al., 1990), with or without necrotic enteritis (F. A. Uzal, unpublished observations). Cholangiohepatitis alone can cause downgrading of chickens at slaughter. However, when cholangiohepatitis occurs alone, it presents as a subclinical condition, and no disease has been reported in on-farm stocks (Onderka et al., 1990). Gross pathological changes consist of pale spots on the superficial (Fig. 19) and cut surfaces of the liver, which histologically correspond to multifocal hepatitis with bile duct proliferations, multiple granulomas, and degeneration of hepatocytes (Onderka et al., 1990). A condition with gross and histological lesions identical to the natural condition has been experimentally reproduced in chickens by either tying off the bile ducts or injecting *C. perfringens* into the ducts (Onderka et al., 1990).

South American Camelids It has been suggested that *C. perfringens* enterotoxemia is the most serious disease of neonate alpacas in Peru (Fowler, 1998). Animals are generally 3–80 days of age when affected, the onset of disease is rapid, and lethality is almost 100% (Fowler, 1998). Adults are rarely, if ever, affected. Clinically, the disease is characterized by sudden death or neurological signs, while the most strik-

Fig. 18. Necrotic enteritis of chickens by *C. perfringens* type A.

Fig. 19. Cholangiohepatitis of chickens by *C. perfringens* type A.

ing gross postmortem changes are pulmonary edema, serosal petechyation, edema and hyperemia of the intestinal tract mucosas with the intestine distended with watery fluid (Fowler, 1998).

Other Animal Species Disease by *C. perfringens* type A has also been reported in minks (Macarie et al., 1980), dogs (Songer, 1996), muskrats (Vustina, 1988), camels (Seifert et al., 1992), ferrets (Songer, 1996) and water buffaloes (Worrall et al., 1987).

Clostridium perfringens Types B and C

Sheep *Clostridium perfringens* types B and C produce similar diseases in sheep from a clinical point of view. These illnesses are characterized by sudden death or acute neurological signs with or without hemorrhagic diarrhea (Barker et al., 1993; Lewis, 2000). Lamb dysentery and hemorrhagic enteritis (*C. perfringens* type B)

occur in lambs under 3 weeks of age, while struck (*C. perfringens* type C) is a condition of adult sheep (Lewis, 2000).

Lamb dysentery usually affects strong lambs that ingest large quantities of milk. Offspring of heavy milking breeds are therefore most vulnerable (Lewis et al., 1995; Lewis, 1998). The clinical course is seldom longer than a few hours, during which the lamb has abdominal pain, stops suckling, collapses and dies, its feces being semi-fluid and blood-stained. Occasionally the animal survives a few days and can display central nervous signs (Mitchell and Linklater, 1983; Songer, 1996; Lewis, 2000).

Struck is a condition of adult sheep caused by *C. perfringens* type C (Barker et al., 1993; Lewis, 2000). Clinically the disease is characterized by sudden death after a short illness in which diarrhea and signs of abdominal pain can be observed. A disease clinically and pathologically very similar to the natural condition has been successfully reproduced in maturing lambs by intraduodenal infusion of *C. perfringens* type C supplemented with soybean flour as a protease inhibitor (Niilo, 1986).

Clostridium perfringens types B and C in sheep produce similar intestinal lesions consisting of diffuse or multifocal hemorrhagic enteritis, predominantly in the ileum (Fig. 20), with excess sanguineous serous fluid in the abdominal cavity and serosal petechias (Barker et al., 1993). In older animals with lamb dysentery or hemorrhagic enteritis that have survived for a few days, focal symmetrical encephalomalacia (FSE) may be present owing to the action of toxin (Barker et al., 1993; Lewis, 2000).

Goats In goats, descriptions of enterotoxemia by *C. perfringens* types B and C are scant, not very well documented, and definitive confirmation of their role in disease production has not been published (Barron, 1942; Guss, 1977; Songer, 1998).

Cattle Enteritis by *C. perfringens* type C is a rare diagnosis in feedlot cattle less than 10 days of age, characterized clinically by abdominal pain and sometimes neurological signs with acute death (Griner and Bracken, 1953). Lethality is usually close to 100%. The gross and microscopic changes of this condition are similar to those of struck in sheep (Barker et al., 1993).

Horses *Clostridium perfringens* type C causes necrotic enteritis in foals (Dickie et al., 1978; Howard-Martin et al., 1986; Pearson et al., 1986; Drolet et al., 1990; Songer, 1996). Clinically the disease is characterized by an acute course, although it can last as long as two days. Affected animals display depression and have hemorrhagic diarrhea accompanied with dehydration (Howard-Martin et al., 1986). Colic can be occasionally observed (Howard-Martin et al., 1986). At postmortem examination, acute fibrinonecrotic enteritis, multifocal or diffuse, is observed in the jejunum and ileum (Barker et al., 1993; Fig. 21). Large numbers of Gram-positive rods can be seen in mucosal smears and histological sections (Barker et al., 1993; Songer, 1996; Songer, 1996); however, when the animals have survived for relatively long periods, other bacte-

Fig. 21. Necrotic enteritis by *C. perfringens* type C in a foal.

ria may colonize the intestinal lesions making the interpretation of Gram-stained smears and histological sections confusing (Manteca et al., 2002; F. A. Uzal, unpublished observations). Terminal toxemia may result in widespread edema and hemorrhages (Barker et al., 1993).

Pigs *Clostridium perfringens* type C produces necrotic enteritis in neonatal pigs. It has been stated that the pig is the most commonly affected species by the type C of this microorganism (Fitzgerald et al., 1988; Johnson et al., 1992; Pace et al., 1992; Songer, 1996). The disease can have up to 50% morbidity in a given herd (Niilo, 1988; Ohnuna et al., 1992) and lethality of 50–100% (Songer, 1996). Clinically, the disease is acute or peracute, with a clinical course lasting less than 24 h, in 1–2 day-old piglets (Mackinnon, 1989). Depression and bloody diarrhea are the main clinical signs in young piglets, although older animals can have diarrhea without blood (Niilo, 1988). Postmortem findings consist of necrotic enteritis with thick hemorrhagic exudate in the lumen. The necrosis of the intestinal wall can affect all layers of the intestine (Field and Gibson, 1955; Arbuckle, 1972; Mackinnon, 1989; Cho et al., 1991; Ohnuna et al., 1992). High intestinal counts of *C. perfringens* are a common finding in this condition (Songer, 1996).

Other Species Gastrointestinal disease has been reported in dogs and chickens with *C. perfringens* type C infection (Songer, 1996) and in South American camelides (Fowler, 1998).

Clostridium perfringens Type D

Sheep *Clostridium perfringens* type D produces a peracute to chronic neurological condition in sheep. The condition is characterized clinically by sudden death or acute to chronic neurological signs including blindness, opisthotonos, convulsions, bleating and recumbency. Respiratory difficulty is an almost constant clinical sign. Diarrhea can occasionally be observed, although this is not a common clinical sign in sheep (Lewis, 2000; Uzal, 2004a, 2004b).

Several gross findings such as excess pericardial fluid with or without fibrin strands (Fig. 22), excess pleural fluid, serosal and pericardial petechyation (Fig. 23) and lung edema (Fig. 24) are common gross postmortem changes of the disease in sheep (Barker et al., 1993; Uzal et al., 2004b). Relatively mild intestinal changes consisting of hyperemia of the small intestine with slight to markedly red fluid contents (Fig. 25) and occasional colitis have been reported in some cases of type D enterotoxemia in sheep (Barker et al., 1993). However, contrary to the popular belief among many producers and veterinarians,
Fig. 22. Excess of pericardial fluid with fibrin strands in a lamb with type D enterotoxemia.
Fig. 23. Epicardial petechiae in a lamb with type D enterotoxemia.

gross intestinal changes are rarely present in sheep enterotoxemia by *C. perfringens* type D. The kidney lesion from which the disease gets its name (pulpy kidney disease) is considered to be a postmortem change (Barker et al., 1993; Uzal et al., 2004b) and is not seen in animals recently dying from type D enterotoxemia (Uzal et al., 2004b)

In a relatively low percentage of acute cases of the disease, herniation of the cerebellar vermis through the foramen magnum of the occipital bone can be seen, while in chronic cases of the disease FSE, a condition characterized by dark-hemorrhagic foci in corpus striatum, thalamus, midbrain and cerebellar white matter cores (Hartley, 1956; Buxton and Morgan, 1976; Buxton et al., 1978b) can be seen. Less consistently, FSE has also been found in cerebral cortex, pons, medulla and white matter of the occipital pole (Buxton et al., 1978b). Hyperglycemia and glycosuria can be found in approximately 50% of affected animals (Uzal et al., 2004b).
Fig. 24. Stable froth in the trachea indicating lung edema in a lamb with type D enterotoxemia.

Fig. 26. Proteinaceous perivascular edema in the basal ganglia of a sheep with *C. perfringens* type D enterotoxemia. Hemotoxylin and eosin, 125×.

Fig. 25. Mild diffuse hyperemia of the small intestine in a lamb with *C. perfringens* type D enterotoxemia.

Fig. 27. Focal symmetrical encephalomalacia in the cerebellar peduncles of a lamb with type D enterotoxemia. HE stain, 12×.

Histologically, the most consistent change of *C. perfringens* type D enterotoxemia in sheep is perivascular proteinaceous edema of the brain (i.e, acidophilic lakes of protein surrounding small and medium sized arteries and veins; Buxton et al., 1978b; Hornitzky and Glastonbury, 1993; Fig. 26). This change can be seen in animals a few hours after the onset of clinical signs and is also known as microangiopathy. The histological picture of FSE (Fig. 27) consists of degeneration of white matter, hemorrhage, astrocyte and axonal swelling and presence of vacuolated macrophages (gitter cells; Buxton et al., 1978b; Fig. 28). Although it is always assumed that microangiopathy is a constant change of type D enterotoxemia of sheep (Hornitzky and Glastonbury, 1993), most descriptions of microscopic lesions in the brain of sheep with enterotoxemia are based on experimental cases (Buxton and Morgan, 1976; Buxton et al., 1978b), and little information is available about these lesions in natural cases of the disease (Buxton, 1978a).

Buxton and Morgan (1976) suggested that brain lesions associated with toxin are due to the

Fig. 28. Large number of vacuolated macrophages (gitter cells) in an area of degeneration and malacia in the brain of a lamb with type D enterotoxemia. Hemotoxylin and eosin, 400×.

action of this toxin on endothelial cells, which generates perivascular edema followed by hypoxia and necrosis of the perivascular tissues. These authors suggested that toxin produced in

the small intestine and absorbed into the systemic circulation reacts with specific receptor sites in the brain of sheep, causing vascular endothelial cells to degenerate. This causes an alteration in fluid dynamics, which in turn causes the astrocyte end-feet to swell and rupture. Serum proteins and eventually red blood cells leak out and the resultant brain edema and hemorrhage produce the clinical nervous signs and the histopathological changes seen in cases of acute intoxication of sheep. However, Finnie et al. (1999) recently showed that toxin can also leak into the brain and act directly on rat neurons producing degeneration and necrosis of these cells in cases of subacute or chronic toxin intoxication. The intimate mechanism of action of toxin remains unknown and requires further investigation.

Goats Naturally occurring enterotoxemia by *C. perfringens* type D in the goat occurs in three forms: peracute, acute and chronic (Shanks, 1949; Oxer, 1956; Smith and Sherman, 1994). The peracute form occurs more frequently in young animals and is similar to the peracute form of the disease in sheep, with animals often found dead without clinical signs having been observed (Shanks, 1949; Oxer, 1956; Blackwell et al., 1991; Blackwell and Butler, 1992). The clinical course is usually less than 24 h and the lethality is always 100% (Smith and Sherman, 1994). The acute form is more frequently seen in adult goats (Smith and Sherman, 1994) and is characterized by diarrhea, abdominal discomfort, severe shock with cold extremities, opisthotonos and convulsions. The diarrhea may be initially yellow-green and pasty but rapidly becomes watery and mucoid with shreds of bowel mucosa and blood (Baxendell, 1988). This form of the disease usually results in death within 2–4 days after the onset of clinical signs, although in a few reported cases animals have recovered following treatment (Baxendell, 1988; Blackwell et al., 1991). The chronic form of the disease occurs in adult animals (Smith and Sherman, 1994), and clinical signs include profuse, watery diarrhea (often containing blood and mucus), weakness, anorexia, signs of abdominal discomfort, and agalactia (Blackwell and Butler, 1992). This form may last for days or weeks and is characterized by diarrhea and progressive weight loss (Shanks, 1949), and it may culminate in death or recovery (Blood et al., 1983).

As in sheep, hyperglycemia and glycosuria can be found in goats with enterotoxemia, although in a lower percentage than in sheep (approximately 25% of the animals) (Blackwell and Butler, 1992).

Gross postmortem changes can be completely absent in peracute cases of the disease, while an excess of pericardial fluid with or without fibrin, serosal hemorrhages, subendocardial hemorrhages, and a fibrino-necrotic colitis (Fig. 29) with colonic serosal edema are usually seen in acute cases of the disease. Diffuse, fibrino-necrotic colitis is the most prominent postmortem finding in chronic enterotoxemia of goats by *C. perfringens* type D (Blackwell et al., 1991; Barker et al., 1993; Uzal and Kelly, 1996).

Descriptions of histopathological changes in naturally occurring enterotoxemia of goats are scant. Microangiopathy and focal symmetrical degeneration have been observed in a few cases of peracute and acute enterotoxemia type D in goats, although these changes seem to be less common than in sheep (Blackwell et al., 1991; Uzal et al., 1997b). In acute and chronic cases of the disease, there is a fibrino-necrotic colitis (Fig. 30) with large numbers of Gram-positive rods (Blackwell et al., 1991; Blackwell and Butler, 1992). Although some authors have claimed that degeneration of the renal proximal tubular epithelium occurs in type D enterotoxemia of
Fig. 29. Fibrino-necrotic colitis in a goat with *C. perfringens* type D enterotoxemia.
Fig. 30. Fibrino-necrotic colitis in a goat with chronic *C. perfringens* type D enterotoxemia. HE stain, 200×.

goats (Barker et al., 1993), this change has not been reported by most authors, and it is likely that, as in sheep, it represents a postmortem phenomenon.

It is not well understood why adult goats develop colitis, a lesion rarely seen in sheep type D enterotoxemia, and systemic lesions are rarely observed in these animals. Although it has been suggested that there could be a differential susceptibility in sheep and goats to the action of toxin on the small and large intestine (Blackwell et al., 1991), recent experiments have shown that when intestinal loops of sheep and goats are exposed to the action of toxin, they react in a similar way, namely colitis and no gross or histological changes in the small intestine (Fernandez Miyakawa and Uzal, 2002). The same experiment showed that fluid accumulation in the small intestine of animals treated with toxin is more marked in goats than in sheep. A more rapid toxin-induced accumulation of fluid in the small intestine of goats could more quickly flush away bacteria and toxin, moderating the intestinal toxin absorption. In contrast, the delayed physiological response in the small intestine of sheep might result in a greater absorption of toxin from the small intestine of this species. This hypothesis is reinforced by the fact that, when toxin is injected intravenously in kids or lambs, the clinical signs and the speed at which they develop are very similar in both species (Uzal and Kelly, 1997a). Other factors, such as the speed of toxin production by different strains of *C. perfringens* type D and the activity of other toxins, bacteria or parasites, might also be responsible for the different clinical signs observed in goats and sheep.

Cattle The literature on enterotoxemia in cattle is scant and sometimes contradictory. For instance, Barker et al. (1993) stated that lesions in calves dying of enterotoxemia caused by *C. perfringens* type D closely resembled those in lambs, including the brain changes typically described for sheep (Figs. 26–28). However, we could not find any firm support for this in the literature. The only report suggesting that brain lesions occur in bovine enterotoxemia is the description by Buxton et al. (1981) of brain lesion in calves, which closely resembled the FSE produced by *C. perfringens* type D toxin in sheep (Hartley, 1956). However, Buxton et al. (1981) did not attempt to test gut samples from their cases for the presence of toxin. Uzal et al. (2002b) injected calves intravenously with *C. perfringens* type D toxin and produced an acute neurological disease and histopathological lesions in the brain identical to those observed in acute enterotoxemia in sheep (microangiopathy; Fig. 31). These results indicate that cattle are
Fig. 31. Perivascular proteinaceous edema (microangiopathy) in the brain of a calf inoculated intravenously with *C. perfringens* type D toxin. HE stain, 125×.

susceptible to the action of toxin, but they do not necessarily imply that the disease occurs naturally in cattle.

Clostridium perfringens Type E

Sheep and Cattle *Clostridium perfringens* type E has been associated with intestinal disease in calves (Hart and Hooper, 1967; Meer and Songer, 1997; Billington et al., 1998), but it has been suggested that type E isolates are not a common cause of enterotoxemia in lambs (Songer, 1998). However, little information is available about this condition in these species.

Rabbits *Clostridium perfringens* type E is responsible for enterotoxemia in rabbits (Baskerville et al., 1980, Percy and Barthold, 2001). The disease has acute, subacute and chronic forms. Diarrhea and sudden death are the main clinical signs of the acute form. At postmortem examination, a carcass in good nutritional condition and perineal soiling with feces are usually the only gross findings in acute cases. In subacute and chronic cases, the carcasses may be thin and dehydrated and straw colored fluid may be present in the peritoneal cavity, together with ecchymosis on the cecal serosa, epicardium and thymus. The cecum is dilated with watery to mucoid content. The wall may be thickened due to submucosal edema. In acute cases, there are usually no histological changes and in the subacute and chronic forms, the most striking histological lesion is necrotizing typhlitis with relative sparing of the crypt bases and lamina propria and large number of Gram-positive rods (Percy and Barthold, 2001).

Clostridium perfringens Enterotoxin Some strains of all *C. perfringens* types, except type E, can produce enterotoxin (CPE; Songer, 1996;

Kokai-Kun and McClane, 1997b). Information about the role of CPE in human disease is plentiful, and CPE positive strains have been isolated from the intestine and feces of many animal species (Van Baelen and Devriese, 1987; Van-Damme-Jongsten et al., 1990). However, with the exception of the dog, very little scientific information is available about the role and pathogenesis of this toxin in diseases of domestic animals. Furthermore, intestinal contents or feces from sick or dead animals are very rarely investigated for the presence of CPE, and no diagnostic criteria have been established for CPE-produced diseases in most animal species.

Dogs This animal has been most studied in terms of the veterinary pathogenesis of CPE. In this species, hospital-acquired diarrhea is associated with CPE-positive *C. perfringens* (Carman and Lewis, 1983; Kruth et al., 1989).

Pigs CPE is not an infrequent finding in stools and intestinal content of pigs with diarrhea (Nabuurs et al., 1983; Popoff and Jestin, 1985; Collins et al., 1989; Estrada Correa and Taylor, 1989) and mild necrotic or degenerative changes in their small intestine (Nabuurs et al., 1983).

Foals The results of several studies suggest that CPE is responsible for intestinal disease (Kanoe et al., 1990; Staempfli et al., 1991). It has also been suggested that this toxin is involved in colitis X (Blood et al., 1983), although no evidence has been provided to either support or rule out this possibility.

Clostridium perfringens β2 Toxin The newly discovered *C. perfringens* β2 toxin has been associated with several diseases of animals (Gibert et al., 1997; Herholz et al., 1999; Gkiourtzidis et al., 2001; Manteca et al., 2002). However, to date, information about the role of this toxin in diseases of animals is scarce. *Clostridium perfringens* type A, producing α and β2 toxin, has been isolated from piglets and horses with necrotic enterocolitis (Gibert et al., 1997; Herholz et al., 1999). Because the role of α toxin in production of digestive lesions is controversial, it has been suggested that it is the β2 toxin that plays a role in causing digestive disease in horses (Herholz et al., 1999). A synergistic role of the α and β2 toxins in the production of necrotic and hemorrhagic enteritis in cattle has been postulated (Manteca et al., 2002). Beta2-positive *C. perfringens* strains were also isolated from lambs with dysentery, and it has been suggested that this toxin may also play a role on the production of this disease (Gkiourtzidis et al., 2001).

The implication of β2 toxin in animal disease is mostly based on a higher prevalence of β2-positive *C. perfringens* strains isolated from animals with enteritis than from normal controls (Gibert et al., 1997; Herholz et al., 1999; Manteca et al., 2002). Although these results suggest that β2 toxin could play an important role in the pathogenesis of enteric disease of several animal species, more research is necessary to clarify this. In particular, the use of this toxin in experimental animal models and the development of diagnostic techniques to detect the preformed toxin in clinical samples are necessary before the natural disease can be characterized and diagnostic criteria for infection involving β2-positive *C. perfringens* can be established.

DIAGNOSIS As mentioned before, *C. perfringens* can be a normal inhabitant of the intestines of most animal species (Niilo, 1965; Niilo, 1980; Itodo et al., 1986; Uzal and Marcellino, 2002a), including humans (Jansen, 1960). This fact makes the diagnosis of infections by *C. perfringens* challenging, and in most cases, the mere isolation of this microorganism from clinical specimens has no diagnostic value. Other criteria need to be taken into consideration for the diagnosis of infections by *C. perfringens* in animals. We discuss here the most commonly used criteria for the diagnosis of these infections.

Clinical History Since the pathogenesis of most *C. perfringens* infections involving rapid multiplication of the organism in the intestine with subsequent production of toxins, a history of sudden change in diet, particularly to a diet rich in carbohydrates, is usually suggestive of a possibility of enterotoxemia in most animal species (Bullen, 1952; Blood et al., 1983).

Prolonged antibiotic treatment is also an important precedent for consideration in cases of necrotic enteritis of horses, pigs and chickens (Songer, 1996).

Age is another important factor to consider when establishing a presumptive diagnosis of *C. perfringens* infection, as several of these conditions are age-specific. For instance, lamb dysentery from *C. perfringens* type B is almost exclusively observed in lambs that are one to a few days old, but *C. perfringens* type D enterotoxemia in this species is very rarely seen in lambs less than 2 or 3 weeks old (Lewis, 2000).

Vaccination history is frequently used by animal owners and veterinarians to rule out infections by *C. perfringens* (Uzal, 2004a). However, several factors (including variation in the quality of *C. perfringens* vaccines between countries and manufacturers and errors of transportation, storage and administration of these vaccines) make vaccination history not always reliable. In addi-

tion, inter- and intraspecies variation in intensity and duration of antibody responses occur frequently in several animal species (Bullen and Batty, 1957; Blackwell et al. 1983; Uzal et al., 1998b), while the kinetics of antibody production in many species is not known.

While no diagnosis of *C. perfringens* infections can be based on clinical history alone, the absence of these precedents should not, under any circumstance, be used to preclude a possible diagnosis of these diseases.

Clinical Signs Clinical signs are, at most, suggestive of *C. perfringens* infections (Uzal, 2004a), and no final diagnosis can be based on clinical grounds only. They vary according to the type of *C. perfringens* involved.

Clostridium perfringens Type A In sheep, sudden death, together with jaundice, can be suggestive of *C. perfringens* type A enterotoxemia (McGowan et al., 1958). However, there are several other more prevalent causes of jaundice in sheep.

Increased mortality with bloody diarrhea should be considered highly suggestive of necrotic enteritis by *C. perfringens* type A in chickens (Prescott, 1979; Kaldhusdal and Hofshagen, 1992). However, some cases of *C. perfringens* type A necrotic enteritis in chickens may not have bloody diarrhea (Songer, 1996).

In other animal species, until more information is available about the syndromes produced by *C. perfringens* type A, clinical signs are of little value in establishing a presumptive diagnosis of these infections.

Clostridium perfringens Types B and C In sheep, sudden death or acute neurological signs, with or without hemorrhagic diarrhea, are suggestive of *C. perfringens* type B or C infection (King, 1980; Lewis, 2000; Uzal, 2004a). These signs in lambs under 3 weeks of age are suggestive of lamb dysentery or hemorrhagic enteritis (*C. perfringens* type B), while similar signs in adult sheep are suggestive of struck (*C. perfringens* type C; King, 1980; Lewis, 2000; Uzal, 2004a). In pigs, high morbidity and mortality with bloody diarrhea in young pigs or bloodless diarrhea in older pigs are suggestive of *C. perfringens* type C infection (Songer, 1996). In other animal species, clinical signs of *C. perfringens* type C infection are of little value in establishing a presumptive diagnosis of this disease.

Clostridium perfringens Type D In sheep and goats, sudden death without clinical signs being observed or short course neurological signs are strongly suggestive, although not specific, of acute *C. perfringens* type D enterotoxemia (Lewis, 2000; Uzal, 2004a). Neurological signs that last for 24 h to several days without other clinical signs are suggestive of subacute or chronic type D enterotoxemia in sheep (Uzal, 2004a). In goats, neurological signs with hemorrhagic diarrhea are suggestive of acute enterotoxemia, while hemorrhagic diarrhea that can last for several days is suggestive of the chronic form of the disease (Blackwell and Butler, 1992). Because recent evidence (Uzal et al., 2002b) suggests that *C. perfringens* type D can cause neurological disease in cattle, animals with acute neurological disease, in the absence of any other clinical signs, should also be investigated for type D enterotoxemia.

Clostridium perfringens Type E Because very little information is available about *C. perfringens* type E infection in most animal species, no presumptive diagnosis of infection by this microorganism can be established on the basis of clinical signs. An exception to this statement is the rabbit, in which enterotoxemia by *C. perfringens* type E is a well-defined entity in which sudden death of well-nourished animals or chronic disease with diarrhea, dehydration, and loss of appetite are clinical signs suggestive of this condition (Rehg and Pakes, 1982; Percy and Barthold, 2001).

Necropsy Findings

Clostridium perfringens Type A In sheep, generalized icterus, enlarged, pale and friable livers and red urine in the urinary bladder are characteristic, although not specific, of type A enterotoxemia (McGowan et al., 1958). However, *C. perfringens* type A enterotoxemia of sheep is a rare disease and other conditions, such as copper toxicity, should be considered before and in the list of differential diagnosis.

In goats, pathology of disease by *C. perfringens* type A is not well documented and the lesions described are not specific for this condition.

In cattle, hemorrhagic enteritis in young calves has been suggested as being associated with *C. perfringens* type A infection (Songer, 1996). However, since the role of this microorganism in disease of cattle has not been finally established, postmortem findings are of little value for the diagnosis of this condition. Cases of hemorrhagic enteritis in which other etiological agents have been ruled out should, anyway, be investigated for *C. perfringens* type A.

In chickens, necrotic enteritis with hemorrhagic sluggish intestinal content, associated or not with cholangiohepatitis, is highly suggestive of *C. perfringens* types A necrotic enteritis (Ficken et al., 1997).

Clostridium perfringens Types B and C Hemorrhagic enteritis in young lambs is suggestive of *C. perfringens* type B infection, while similar findings in adult sheep are suggestive of struck by *C. perfringens* type C (Lewis, 2000; Uzal, 2004a). Also, in older animals, hemorrhagic enteritis and focal symmetrical encephalomalacia (FSE; see below) are pathognomonic changes of *C. perfringens* type B infection (Lewis, 2000).

In goats, pathology of diseases by *C. perfringens* types B and C are not well documented, and the lesions described are not specific for these conditions (Barron, 1942, Gkiourtzidis et al., 2001; Uzal, 2004a).

In calves a few days old, *C. perfringens* type C produces necrohemorrhagic enteritis and these changes are characteristic but not specific for the condition (Barker et al., 1993).

In young foals with diffuse acute hemorrhagic enteritis in the jejunum and ileum, *C. perfringens* type C infection should be included in the list of differential diagnosis. These changes are, however, not specific for the condition (Howard-Martin et al., 1986).

In young (1–2 day-old) piglets, necrotic hemorrhagic enteritis is highly suggestive of *C. perfringens* type C enterotoxemia (Songer, 1996). In older animals (1–2 weeks of age), jejunal mucosa necrosis with nonbloody diarrhea is characteristic, although not specific for type C infection (Songer, 1996).

Clostridium perfringens Type D In sheep, FSE, when present, is pathognomonic and diagnostic for type D enterotoxemia (Hartley, 1956; Hornitzky and Glastonbury, 1993). However, this lesion is very rarely seen (F. A. Uzal, unpublished observation). Cerebellar coning as a consequence of brain edema is more frequently seen in cases of this disease and, although not specific for enterotoxemia, the presence of this lesion is highly suggestive of *C. perfringens* type D enterotoxemia (Uzal, 2004a). Other changes such as excess pericardial and/or pleural fluid and lung edema are suggestive but by no means specific of this disease. Gross changes may be entirely absent in a few cases of sheep enterotoxemia by *C. perfringens* type D (Barker et al., 1993; Uzal et al., 2004b). A negative necropsy should not, therefore, rule out enterotoxemia, and this disease should be included in the list of differential diagnosis for sudden death in sheep without gross postmortem findings. The so-called "pulpy kidney" lesion is considered a postmortem phenomenon (Barker et al., 1993; Uzal et al., 2004b) and has therefore little, if any, diagnostic significance.

In enterotoxemia by *C. perfringens* type D in goats, there may be changes that are suggestive of the disease, but none of these alterations is pathognomonic of enterotoxemia (Uzal, 2004a). Among these are excess pericardial fluid and lung edema in peracute and acute cases of the condition and fibrino-necrotic colitis in acute, subacute and chronic cases. Gross changes may be entirely absent in a few cases of caprine enterotoxemia by *C. perfringens* type D (Blackwell and Butler, 1992), and negative necropsy in animals with sudden death should not be used to rule out a diagnosis of enterotoxemia in goats.

Ancillary Tests There are a few diagnostic ancillary tests that are specific for *Clostridium perfringens* enterotoxemias. Among these are glucose detection in urine of sheep and goats with *C. perfringens* type D enterotoxemia. The presence of this metabolite in urine of these animals is usually interpreted as strongly suggestive of enterotoxemia. However, approximately 50% of the animals with type D enterotoxemia have no glycosuria (Uzal et al., 2004b) and although glycosuria is a useful indicator of the possibility of type D enterotoxemia, the converse does not apply, i.e., absence of glycosuria does not rule out a diagnosis of enterotoxemia in either species.

Other ancillary tests, such as observation of Gram-stained smears of intestinal mucosa can also be used to establish a presumptive diagnosis of enterotoxemia by any of the types of *C. perfringens* in most animal species. To be considered as a positive indicator of enterotoxemia, the Gram smears should show a large amount of Gram-positive rods with rounded ends, and although other bacterial forms can be seen, there should be a preponderance of rods (Carter, 1984; Fig. 32). Although it also has presumptive diagnostic value when it is positive, as with the case of glycosuria, Gram-stained smears of the intestinal mucosa cannot be used to rule out a diagnosis of enterotoxemia if they are negative.
Fig. 32. Gram-stained smear of the small intestine mucosa of a goat with *C. perfringens* type D enterotoxemia.

Histopathology

Clostridium perfringens Types A, B and C The histopathological changes of infections by *C. perfringens* types A, B and C in most animal species are not specific and therefore do not have specific diagnostic significance, although they can be suggestive of these diseases.

Clostridium perfringens Type D In sheep, the histopathological changes produced by *C. perfringens* type D toxin in the brain (i.e., microangiopathy and/or focal symmetrical necrosis) are unique and pathognomonic for this type of enterotoxemia (Hornitzky and Glastonbury, 1993). These changes are valuable diagnostic criteria for diagnosis of type D enterotoxemia, particularly when results of toxin investigation in intestinal contents are not available.

It is unclear how frequently sheep dying from enterotoxemia fail to develop microangiopathy, although cases of enterotoxemia in which this lesion has not been seen are occasionally diagnosed (Uzal et al., 2004b). While cerebral microangiopathy is a useful indicator of enterotoxemia, the absence of this lesion does not preclude a diagnosis of this disease in sheep.

Although changes in the brain are not considered to be a common feature of caprine enterotoxemia by *C. perfringens* type D, microangiopathy and symmetrical degeneration of the brain may be observed in peracute and acute cases (Barker et al., 1993; Uzal et al., 1997b).

Histological lesions in the kidneys are not a characteristic of sheep, goat or cattle enterotoxemia, as the changes frequently described in cases of this disease are believed to be postmortem changes due to rapid autolysis of the tissues (Barker et al., 1993).

Clostridium perfringens Type E Except for the rabbit, descriptions of histological lesions by *C. perfringens* type E in animals are scant. In rabbits the histological changes of infection by *C. perfringens* type E are not specific for the condition (Percy and Barthold, 2001), although they may be used to establish a presumptive diagnosis of the condition.

Culture and/or PCR Detection Because all *C. perfringens* types can be normal inhabitants of the intestine of most animals, the mere culture of this microorganism from intestinal contents of animals is not diagnostic for infections by any type of this microorganism. However, quantitation of *C. perfringens* in intestinal content is considered an indicator of disease occurrence in animals (Wierup and DiPietro, 1981; Dart, 1988; Ohnuna et al., 1992) when large amounts of

C. perfringens, usually above 10^7 colony forming units (CFU)/g of intestinal contents or feces, are found. This appears true for *C. perfringens* type A and D enterotoxemias of lambs, in which elevated counts of *C. perfringens* are found in intestinal contents (usually, 10^4 to 10^7 CFU/g) and for cases of *C. perfringens* type C infection in piglets from which as many as 10^9 CFU of *C. perfringens* types A or C were isolated (Popoff, 1984; Ohnuna et al., 1992; Songer, 1996). However, high numbers of *C. perfringens* sometimes occur in the normal gut (Songer, 1996), and information about normal counts and their variations in most animal species is scant.

In sheep, while most authors seem to agree that the isolation of types A and D is of no diagnostic value, some researchers still believe that the isolation of types B or C is in itself of diagnostic value (Sterne and Batty, 1975). However, this latter belief is undermined by the fact that *C. perfringens* types B and C have been found in the intestinal content of healthy sheep (Itodo, 1986; Uzal and Marcellino, 2002a). More studies to assess the amounts of the different toxinotypes of *C. perfringens* in intestinal contents and feces of normal animals are necessary to clarify this point.

Several recent studies used PCR assays in attempts to correlate the intestinal presence of *C. perfringens* carrying different toxin genes with disease (Garmory et al., 2000; Gkiourtzidis et al., 2001). This approach is particularly useful in the case of toxins, such as β2, for which no detection assays are currently available. More information about the occurrence of the different toxin genes in isolates from healthy animals is necessary, however, to determine whether these genes correlate with disease.

Toxin Detection The most accepted criterion in establishing a definitive diagnosis of disease by *C. perfringens* in several animal species is the detection of its toxins in intestinal contents (Sterne and Batty, 1975). However, some of the major toxins of *C. perfringens* (e.g., α toxin) can also be found, albeit in small amounts, in the small intestine of clinically healthy sheep, goats and other animal species (Bullen, 1952). This poses a diagnostic challenge, because to the best of our knowledge there is no information about the levels of the toxin normally present in the intestine of clinically normal animals vs. diseased animals.

Probably one of the greatest impediments to the detection of *C. perfringens* toxins in body fluids is that very few diagnostic laboratories around the world perform toxin detection routinely. Furthermore, only a few commercial diagnostic systems are available, and those are for detection of only a few of the major *C. perfrin-*

gens toxins. Antibodies for the traditionally used mouse neutralization test are no longer commercially available.

Minimal standardization exists between different laboratories or techniques for *C. perfringens* detection. This is evident from a recent evaluation and comparison of four techniques used by four different diagnostic laboratories to detect *C. perfringens* type D toxin in intestinal contents and other body fluids of sheep and goats (Uzal et al., 2003). This study showed a marked inconsistency among the four techniques employed, suggesting that until more information is available about the reliability of these techniques, the diagnosis of *C. perfringens* infections should not be based solely on toxin detection but also on consideration of clinical and pathological data.

While detection of and β toxins (by any of the methods currently available) in intestinal contents of animals suspected to have died of enterotoxemia is considered diagnostic for this disease, failure to detect these toxins should not exclude a diagnosis of enterotoxemia. This is particularly true for β toxin, which is very sensitive to the action of trypsin and can be destroyed after a few hours presence in the intestine (Sterne and Batty, 1975). Epsilon toxin is a much more robust toxin that can remain active for up to 48 weeks at 4°C (Bennett, 1961). However, failure to detect this toxin in intestinal contents of sheep does not rule out a diagnosis of enterotoxemia if the pathological changes (i.e., microangiopathy and/or focal symmetrical degeneration of the brain) are present (Buxton et al., 1978b).

PREVENTION Prevention of most *C. perfringens* enteric infections of animals is based mainly on nutritional management (Bullen, 1952) and vaccination (Kennedy et al., 1977; Odendaal et al., 1989; Lewis, 2000). The latter applies only to those conditions for which vaccines are commercially available.

As would be expected, prevention is best understood for those conditions in which the epidemiology and pathogenesis are better known. This is the case for type D infections in sheep and goats and type C infection in piglets.

Nutritional management to prevent cases of type D enterotoxemia in sheep and goats mainly involves avoiding sudden changes in diet, particularly from poor rations to diets rich in highly fermentable carbohydrates (Bullen, 1952). A minimum of two weeks with daily progressive increase of the new diet should be allowed for the ruminal microflora to adapt to the new ration (Merchen, 1988).

Most clostridial commercial vaccines are multivalent, including antigens from several clostrid-ial species in addition to *C. perfringens* antigens. The *C. perfringens* components of these vaccines typically consist of inactivated cells, toxins or both (Hjerpe, 1990; Songer, 1996). The immunogenic value of the *C. perfringens* bacterial cells is, however, doubtful, and the potency control of the *C. perfringens* vaccines is based on the ability of the toxoids to generate antibodies in laboratory animals (Anonymous, 1993).

Currently, vaccines containing α, β and toxoid are commercially available. These vaccines are used regularly in most countries of the world in sheep. In this animal, vaccination with vaccines containing β and toxoid drastically reduces the occurrence of disease by types B, C and D of *C. perfringens*. Two initial doses of vaccine are recommended when lambs are 4–6 months of age, followed by an annual booster 4–6 weeks before lambing (Lewis, 2000), which confers protective levels of colostrum antibodies to the lambs until their first dose of vaccine (Bullen, 1952; Kennedy et al., 1977; Odendaal et al., 1989; Lewis, 2000).

Because no vaccines are manufactured specifically to prevent enterotoxemia in goats, vaccines developed for sheep are generally used in this species (Blackwell et al., 1983). However, in goats these vaccines elicit antibody titers of lower magnitude and shorter duration than in sheep, and although they appear to reduce the incidence and severity of caprine enterotoxemia (Shanks, 1949), these vaccines do not seem to prevent the occurrence of enterocolitis in goats (Shanks, 1949; Oxer, 1956; Guss, 1977; Blackwell et al., 1983). The reason for the difference in the responses of sheep and goats to vaccination with toxoid is not well understood, but it has been suggested this is due to the action of toxin locally in the colon of goats, an environment where serum antibodies produced in response to parenteral vaccination would not be very efficient (Uzal and Kelly, 1996). It has been demonstrated, however, that very high titers of toxin antibodies obtained after experimental parenteral vaccination of goats with oil adjuvanted toxoid vaccines, protect goats against both the systemic and colonic effects of experimental type D enterotoxemia (Uzal and Kelly, 1998a). Blackwell et al. (1983) and Uzal et al. (1998b) recommended that to maintain antitoxin titers at protective levels in goats, it is necessary to vaccinate the animals three to four times a year. Initial vaccination should be followed by a booster 3–6 weeks later, and pregnant females must receive the last vaccination 2–3 weeks before parturition. Kids should receive their first dose at 4–6 weeks of age (Smith and Sherman, 1994).

There are also commercially available vaccines to protect piglets against necrotic enteritis by vaccination of the dams during gestation

(Ripley et al., 1983). Vaccination with these products has reportedly achieved an up to tenfold reduction in mortality (Udovicic et al., 1990).

Although commercial vaccines including α toxoid, in addition to several other toxoids, are available in several countries; no information has been published about the protective effect that these vaccines might have on intestinal or muscle disease caused by *C. perfringens* type A.

It is believed that vaccination with CPE toxoid reduces enteric disease in pigs (Estrada Correa and Taylor, 1989), although to the best of our knowledge no CPE vaccines are commercially available.

Applications

Recent studies suggest the exciting possibility of using CPE as a therapeutic agent against certain solid tumors. One study found that claudin-4, which can serve as a functional CPE receptor, is highly expressed in most pancreatic cancer cells (Michl et al., 2001). This study then demonstrated that direct injection of CPE into pancreatic tumor xenografts (growing in mice) induces necrosis and shrinkage of those tumors.

The promising antitumor activity of CPE is not limited to pancreatic cancer. Overexpression of claudin-3, another functional CPE receptor, has been detected in prostate adenocarcinomas, and these tumor cells were also found to be highly CPE-sensitive (Long et al., 2001).

Clostridium difficile

Clostridium difficile, a sporeforming, Gram-positive anaerobe is an example of an opportunistic pathogen that takes advantage of people with compromised intestinal flora. When the normal intestinal microflora is altered by antibiotics, *C. difficile* can become established and produce its tissue-damaging toxins, resulting in the onset of disease. Nearly all antibiotics have been associated with the disease, but ampicillin, amoxicillin, clindamycin, and cephalosporins are the most common. The resulting infection can range from asymptomatic carriage, to diarrhea, to life-threatening pseudomembranous colitis. Fortunately, new and improved diagnostics are now available so that the disease can be identified before it develops into the severe stages. The general terms used to describe *C. difficile* disease include antibiotic-associated diarrhea (AAD), antibiotic-associated colitis (AAC), and pseudomembranous colitis (PMC). AAD is the milder form of the disease, and in some instances, is self-limiting. AAC and PMC have a strong inflammatory component and may become life-threatening if not accurately diagnosed and treated promptly.

Clostridium difficile causes almost all cases of pseudomembranous colitis, although in a few instances *Staphylococcus aureus* has been suggested by some to cause PMC. The involvement of *S. aureus* was proposed in the 1950s and 1960s prior to the discovery of *C. difficile* as an intestinal pathogen, and many doubt that *S. aureus* was ever involved. However, there are rare instances in which *C. difficile* cannot be cultured or identified by other methods (e.g., detection of toxin by tissue culture or antibody-based tests, or detection of toxigenic strains by PCR) from the patient's stools, indicating that other causes of PMC are rare. *Clostridium difficile* is the most recognized cause of AAD, but this organism causes only 25% or less of these cases. More than 75% of AADs remain undiagnosed.

Because of improved diagnostics, *C. difficile* disease is recognized more promptly, reducing the number of cases that progress to PMC. Current antibiotic regimens used to treat this antibiotic-initiated disease are effective in most cases. However, relapses continue to be a major problem, and the incidence of *C. difficile* disease (primarily AAD) continues to occur at a constant rate. Recent estimates indicate that about 300,000 *C. difficile* cases occur annually in the United States. From an economic perspective, the disease costs roughly $5,000–10,000 per case, with higher costs incurred for relapsing patients. When the costs of diagnosis, therapy, and extended hospital stay are considered, this disease adds more than a billion dollars annually to healthcare costs in the United States.

Historical Perspectives

Clostridium difficile was first described by Hall and O'Toole in 1935 (Hall and O'Toole, 1935). The original isolates, named "*Bacillus difficilis*," because of the difficulty in isolating the organism, were obtained from stool specimens from healthy infants. Although believed to be harmless members of the microflora, the investigators showed the isolates were toxigenic in guinea pigs. The role of this organism in human disease went unnoticed until the late 1970s. Some cases of PMC attributed to *S. aureus* were reported throughout the 1950s and 1960s, but the organism could not be isolated consistently from stool specimens obtained from PMC patients. In addition, *S. aureus* was present in stool specimens from many apparently healthy persons. Since these reports, no additional studies appeared supporting a primary role for *S. aureus* in the onset of PMC.

The importance of PMC as a complication of antibiotic therapy became apparent through the

results of studies done in the mid-1970s. A landmark study by Tedesco et al. (1974) reported a PMC incidence of 10% in patients receiving clindamycin, resulting in the phrase "clindamycin-associated colitis." Within 2–3 years, researchers described the presence of a "cell-rounding" activity in stool specimens from persons with antibiotic-associated PMC (Bartlett et al., 1977; Bartlett et al., 1978; Larson et al., 1977; Rifkin et al., 1977). The rounding of cells was neutralizable by gas gangrene antisera and, more specifically, by *C. sordellii* antisera. However, investigators were unable to recover *C. sordellii* in stool specimens from PMC patients. Further analysis soon led to the discovery of *C. difficile* in the specimens. The role of this organism as the cause of antibiotic-associated diarrhea and colitis was established by a series of studies showing that 1) human isolates of *C. difficile* isolated from PMC patients could be grown in vitro, 2) culture filtrates from these isolates caused the same type of cell rounding as that observed directly in the stool specimens, 3) the activity was neutralized by *C. sordellii* antisera, and 4) hamsters challenged with human PMC isolates developed severe intestinal disease and died. The puzzling cross-neutralization by *C. sordellii* antisera was explained shortly thereafter by results showing that *C. sordellii* produces two toxins immunologically related to those produced by *C. difficile*. Antiserum against the *C. sordellii* toxins cross-reacted and cross-neutralized the toxins from *C. difficile*, resulting in the initial confusion surrounding any role of *C. sordellii* in the disease.

Until the late 1970s, only a single toxin had been discovered. In 1980, Dr. John Bartlett and his research team in the United States (Taylor et al., 1980) and Dr. Ueno's research team in Japan (Banno et al., 1981) identified a second toxin. The first toxin discovered, toxin B, is also referred to as the "cytotoxin." The second toxin, toxin A, often is referred to as the "enterotoxin." The toxins are named "A" and "B" on the basis of their order of elution during anion-exchange chromatography on resins such as diethyl amino ethyl (DEAE) Sepharose and Sephadex. Toxin A binds more weakly owing to its lower negative charge than toxin B and elutes from anion-exchange resins with lower levels of NaCl than toxin B. Therefore, it elutes prior to toxin B. Both toxins are cytotoxic, but toxin B is much more active against most mammalian cells in tissue culture assays than toxin A. Toxin A, on the other hand, is a tissue-damaging enterotoxin that is much more active in the intestinal tract than toxin B in various animal models. Both toxins are lethal when injected systemically, and they appear to act synergistically in the intestine.

Taxonomy and Phylogeny

On the basis of 16S ribosomal RNA sequencing, *C. difficile* is included in cluster XIa of the clostridia. With the exception of *Clostridium sordelli*, that cluster contains no other pathogenic species.

Phenotypically, *C. difficile* closely resembles *C. sporogenes*, although the two species can be differentiated by metabolic properties. The mol% G+C content is 28%. A collaborative effort between researchers in London and the Sanger Institute has led to the sequencing of a toxigenic isolate (*C. difficile* strain 630 type X). The genome is a circular chromosome of 4,290,252 bp with a G+C content of 29.06%. There also is a circular plasmid of 7,881 bp with a G+C content of 28.9% in this strain Sanger Sequencing Center (http://www.sanger.ac.uk/Projects/C_difficile/).

Habitat

Clostridium difficile only thrives in the adult intestinal tract when the normal flora has been altered or compromised, usually by antibiotics. Other drugs such as antineoplastic agents also alter the intestinal flora, predisposing patients to infection with this pathogen. In healthy persons, the intestinal carriage rate is 3% or less, with slightly higher rates reported in Japan (Mulligan, 1988). In contrast to its low carriage rate in adults, *C. difficile* is present in a high number of infants and is (or should be) considered a member of the normal microflora. The organism and its toxins can be detected in a high percentage of infants (in some studies, 50% or higher). The level of colony-forming units and toxin in feces from completely healthy infants may be comparable to the levels observed in feces from adults with severe *C. difficile* disease. It is not understood why there is this difference in susceptibility to disease between infants and adults. The organism persists in the environment in the spore stage, making it extremely difficult to eradicate. In the rooms of *C. difficile* patients, the organism can be isolated from the linens, curtains, books, walls and floor surfaces.

Most studies of this organism have focused on its presence in the intestinal tract where it causes disease. However, *C. difficile* also has been isolated from the genitourinary tract (Hafiz and Oakley, 1975). It is suspected that infants tend to become colonized with the organism through environmental sources.

Clostridium difficile has been isolated from a wide variety of animals. Many animals (horses, camels, cows, donkeys, rabbits, household pets such as dogs, cats and birds) carry low numbers of the organism but do not become ill. Some

animals, however, do develop intestinal illness similar to that observed in humans. Hamsters are extremely sensitive to this organism and its toxins, and develop an acute onset of intestinal disease manifested primarily as a fatal cecitis. For this reason, hamsters are the animal model of choice and have proved valuable for learning more about the pathogenesis and therapeutic aspects of the disease. Antibiotic-treated mice also can develop the disease, but in mice, the disease develops more as a chronic colitis. For this reason, some researchers believe the mouse model more closely mimics the onset of disease in humans. Horses and pigs treated with antibiotics also can develop *C. difficile* intestinal disease.

Isolation

Clostridium difficile requires anaerobic conditions for growth. However, it is not as strict an anaerobe as some of the other clostridia (e.g., *C. tetani*). Cycloserine-cefoxitin-fructose agar (CCFA), originally developed by George et al. (1979), continues to be the most commonly used selective and differential plate media for culturing the organism from stool specimens. The original formulation consists of egg yolk-fructose agar base (Difco Laboratories, Detroit, MI) supplemented with cycloserine (500 µg/ml, final concentration), cefoxitin (16 µg/ml, final concentration), and 5% egg yolk suspension. CCFA is highly selective, but when culturing fecal specimens, some Gram-negative anaerobes, lactobacilli, and other clostridia will grow on the agar. The inclusion of horse blood improves the recovery of the organism (Marler et al., 1992). Other modifications that reportedly improve the recovery of the organism from fecal specimens and environmental sources include 0.1% sodium taurocholate in place of the egg yolk suspension, decreasing the cycloserine and cefoxitin concentrations in half, the addition of cysteine hydrochloride as a growth supplement, and norfloxacin (12 µg/ml, final concentration) and moxalactam (32 µg/ml, final concentration) as the selective agents (Levett, 1984; Bartley and Dowell, 1991; Aspinall and Hutchinson, 1992). On solid media, *C. difficile* gives flat rough colonies that grow to several millimeters in diameter. Under long-wavelength ultraviolet light, the colonies will fluoresce. The intensity of the fluorescence can be increased by the addition of blood or brain-heart infusion, and nonspecific fluorescence may be reduced by the addition of blood to CCFA.

Selective broths may also be used to recover *C. difficile* from stool specimens. Cycloserine-cefoxitin-fructose broth can be prepared using the original formulation of George et al. but omitting the agar. In our laboratory, we routinely use brain-heart infusion broth supplemented with cycloserine (500 µg/ml) and cefoxitin (16 µg/ml). Broth cultures are more easily and efficiently analyzed for *C. difficile* toxin by ELISA or tissue culture than colonies isolated on solid media.

Identification

Clostridium difficile is a Gram-positive anaerobe that produces subterminal spores. The vegetative cells may be motile in broth cultures with peritrichous flagella. The sporulating ability of *C. difficile* varies from strain to strain. Unlike the enterotoxin of *C. perfringens*, spore production of *C. difficile* is not correlated with toxin production. The ability of this organism to form spores is the primary reason that *C. difficile* is such a problem in medical facilities. Laboratories that utilize bacterial culture often use heat-shock procedures or the incorporation of sodium thioglycollate and lysozyme into the isolation medium to improve the recovery of spores from specimens (Wilson, 1983; Clabots et al., 1989; Kamiya et al., 1989). In some strains, capsules and fimbriae may be present. However, these have only been described in a few articles, and their role in the virulence of this organism has not been well characterized (Borriello et al., 1988; Strelau et al., 1989; Davies and Borriello, 1990; Baldassarri et al., 1991). As with spore formation, there is no correlation of capsule or fimbriae production with toxin production.

This organism produces a number of antigens that crossreact with antigens from other clostridia and anaerobes. In addition to the crossreaction of toxins A and B with *C. sordellii* hemorrhagic toxin (toxin HT) and *C. sordellii* lethal toxin (toxin LT), respectively, there are other crossreactive antigens. The cell wall consists of array proteins that are related to cell wall antigens from *C. sordellii* and *C. bifermentans*. There are extractable antigens, including a 36-kDa protein that has been shown to elicit an antibody response in patients with *C. difficile* disease. No function has been assigned to this particular antigen (Poxton and Cartmill, 1982; Masuda et al., 1989; Pantosti et al., 1989; Cerquetti et al., 1992). Glutamate dehydrogenase, also referred to as the "common antigen," crossreacts with the glutamate dehydrogenase from *C. sporogenes*, proteolytic *C. botulinum*, and *Peptostreptococcus anaerobius*. The *C. difficile* enolase is immunologically related to *C. bifermentans* enolase.

Preservation

Anaerobic cultures of *C. difficile* can be lyophilized, and freeze-dried material is stable for

years. The organism also can be preserved for years as spores in cooked meat media. Screw-capped or stoppered tubes of the media can be inoculated with strains and incubated for 24–36 h at 37°C or until there is obvious growth. The tubes can then be stored on the shelf at room temperature with the cultures remaining viable for years.

Physiology

Clostridium difficile needs anaerobic conditions for growth. The organism is nonhemolytic, egg yolk negative, and weakly or nonproteolytic under typical culture conditions. Glucose is utilized as a carbon source, but other sugars, including sucrose, lactose and maltose, are not suitable carbon sources. *Clostridium difficile* produces acetic, isobutyric, butyric, isovaleric, valeric and isocaproic acid through fermentation. The most unusual of these is isocaproic acid (Johnson et al., 1989). Isocaproic acid has been suggested as a marker for the organism, but this fermentative product also is produced by *C. bifermentans*, *C. sordellii* and *C. sporogenes*. Another unusual product is *p*-cresol, which is produced through the metabolism of tyrosine (Levett, 1987; Sivsammye and Sims, 1990). *Clostridium scatologenes*, which is seldom encountered in clinical specimens, is the only other *Clostridium* species known to produce *p*-cresol. Like isocaproic acid, *p*-cresol has been suggested as a marker for *C. difficile* in clinical specimens. However, *p*-cresol has not been utilized because it requires expensive equipment, and its detection does not distinguish toxigenic from nontoxigenic isolates.

Clostridium difficile utilizes *N*-acetyl-glucosamine and *N*-acetyl-neuraminic acid and other substrates through the production of hydrolytic enzymes that include collagenase, some protease, and mucopolysaccharide-hydrolyzing enzymes. In addition, the organism produces arylesterase, sialidase, sialate *O*-acetylesterase, *N*-acetylneuraminate lyase and glycosulfatase (Corfield et al., 1992). These activities allow *C. difficile* to utilize mucin components as its main energy source. These enzymes are produced by many members of the intestinal microflora and are not unique to *C. difficile*.

Toxins

TOXIN GENETICS Both of the genes for toxins A and B have been cloned and sequenced (Von Eichel-Streiber et al., 1988; Von Eichel-Streiber et al., 1992a, 1992b; Dove et al., 1990; Johnson et al., 1990; Barroso et al., 1990). There are five ORFs in the pathogenicity islet encoding toxins A and B (Fig. 33). The *toxB* gene is approximately 1 Kb upstream of the *toxA* gene. Upstream of the *toxB* gene is an ORF (*txeR*) that positively controls regulation of *toxA* and *toxB*. There is a small reading frame located between *toxA* and *toxB* that encodes a potential lipoprotein signal sequence at its N-terminus. The small ORF designated "txe3" is transcribed in the opposite direction of the other genes in the pathogenicity islet. There has been speculation that *txe3* may play a role in negative regulation of *toxA* and *toxB*, but this remains to be determined. None of the small ORFs are involved in the biological activity of either toxin A or toxin B. Recombinant toxin A and toxin B have been expressed from *toxA* and *toxB* cloned independently of the other ORFs. Recombinant toxin A is enterotoxic, cytotoxic, and lethal, and agglutinates rabbit erythrocytes whereas recombinant toxin B is cytotoxic and lethal. Nontoxigenic strains of *C. difficile*, which comprise roughly 20% of the clinical isolates, do not carry any of the ORFs in the pathogenicity islet. Instead, they contain a 127-bp sequence at the locus where the pathogenicity islet is located. This sequence is not present in toxigenic strains. There are inverted repeats with predicted the secondary structure in the sequence, suggesting that this may be an insertion site.

The distance between the transcriptional start site and the ATG start codon is 169 nucleotides for *toxA* and 239 nucleotides for *toxB* (Von Eichel-Streiber et al., 1995; Hammond et al., 1996; Hundsberger et al., 1997; Dupuy and Sonenshein, 1998; Song and Faust, 1998). Under in vitro growth conditions, *C. difficile* produces higher levels of toxins A and B when grown slowly. Other clostridial toxins (e.g., botulinum neurotoxin) also exhibit the property of higher expression during slow growth. Rapid growth, defined media, and glucose all affect toxin production, resulting in lower levels of toxins A and B (Dupuy and Sonenshein, 1998).
Fig. 33. The pathogenicity islet encoding toxins A and B.

The *txeR* element located upstream of *toxB* encodes a small molecular weight protein (Mr 22,000) of 184 amino acids. This protein contains an unusually high number of lysine residues within the C-terminus. Further analysis through protein data libraries (Moncrief et al., 1997) shows the presence of a helix-turn-helix motif with sequence identity to DNA binding bacterial response regulators, including UviA, a positive regulator of bacteriocin production in *C. perfringens* (Garnier and Cole, 1988a; Garnier and Cole, 1988b), *botR* of *C. botulinum*, a positive regulator of botulinum neurotoxin C1 (Marvaud et al., 1998a, 1998b), and *tetR*, a positive regulator of the *C. tetani* tetanus toxin gene (Marvaud et al., 1998b). The putative role of the *txeR* element as a positive regulator is demonstrated by studies showing that when expressed in *trans* with the *toxB* promoter linked to the repeating units of toxin A (designated "toxin A repeating units" [ARU]), the expression of ARU increases 800-fold. Further, when the toxin A promoter is fused to ARU and *txeR* is supplied in *trans*, the expression increases over 500-fold (Moncrief et al., 1997). Some early initial studies on the transcription of *toxA* and *toxB* suggested the possibility that the toxins are transcribed as part of a large polycistronic mRNA and that smaller mRNAs possibly result from post-translational processing (Hammond et al., 1996). However, more recent studies indicate that most of the transcription occurs from the individual toxin gene promoters, and that the *txeR* gene product is involved.

It has been suggested that *txeR* may be a σ factor that turns on toxin production in response to environmental conditions such as limited nutrients (e.g., the conditions that exist in brain heart infusion dialysis sac cultures). In fact, *txeR* actually appears to stimulate its own synthesis (Mani et al., 2002). High-level transcription would then occur as the levels of the *txeR* product increase (Moncrief et al., 2000a, 2000b). This proposed mechanism is supported by recent studies showing that *txeR* encodes a positive regulator that allows an RNA polymerase to recognize the promoters of *toxA* and *toxB*. In addition, *txeR* directly stimulates its own synthesis. These findings support the idea that during rapid growth, *txeR* is repressed and little production of either toxin A or toxin B occurs. During slower growth (e.g., during stationary growth), the repression of *txeR* decreases, resulting in stimulation of *txeR*, and in turn increased transcription of *toxA* and *toxB*.

TOXIN STRUCTURE Toxins A and B are produced as large single polypeptide chains that are released following autolysis as the organism enters stationary phase growth. Neither toxin contains a signal sequence or requires proteolytic activation. Examination of the primary structure of toxins A and B shows that the two toxins are highly related in their basic structure (Fig. 34). This similarity is especially interesting since the two toxins demonstrate no significant immunological crossreaction, and antitoxin A and B antibodies do not cross-neutralize the heterologous toxin (Libby and Wilkins, 1982; Lyerly et al., 1986). The toxins have an overall homology of >45% at the amino acid level. Structurally, both contain a series of contiguous repeating units at the COOH terminus, comprising roughly one-third of the molecule (Price et al., 1987; Lyerly et al., 1989; Von Eichel-Streiber and Sauerborn, 1990; Von Eichel-Streiber et al., 1992b). The repeating portions, which are comprised of large repeating units made up of smaller repeating units, have a homology of approximately 41%. The repeating units of toxin A comprise the temperature-dependent hemagglutinating activity of the molecule. The enzymatic site in each toxin is located upstream near the N-terminus. Several other features are conserved, including four cysteine residues located in almost identical positions, a putative ATP binding region, and a hydrophobic membrane-spanning region located near the center of each toxin.
Fig. 34. Structure/function relationships for *C. difficile* toxins A and B.

The repeating units most likely represent the binding portion of the toxin. In toxin A, the repeating units bind to galactose-containing residues. Mammalian cells that carry Galα1-3Galβ1-4GlcNAc residues are much more sensitive to toxin A than cells that do not have these residues (Wilkins and Tucker, 1989; Tucker et al., 1990). For example, F9 teratocarcinoma mouse cells, which have the galactose-containing residues on their cell surface, are a hundred times more sensitive to toxin A than CHO cells, which lack the galactose residues. Toxin A also binds to human intestinal tissue, although the binding is not mediated through Galα1-3Galβ1-4GlcNAc residues, which are absent in the human intestine. Interestingly, however, toxin A binds to the I, X, and Y (Lewis X [Le^x] and Lewis Y[Le^y]) carbohydrate blood group antigens, all of which are galactose-containing moieties that contain the type 2 core Galα1-3Galβ1-4GlcNAc that binds toxin A (Tucker and Wilkins, 1991). Possible receptors for toxin B have not been identified. Both toxins probably can enter mammalian cells via nonspecific mechanisms such as pinocytosis.

MECHANISM OF ACTION As might be inferred from the high level of homology at the amino acid level, toxins A and B share enzymatic properties. Both are monoglucosyltransferases that covalently modify the cellular protein Rho (Just et al., 1994; Just et al., 1995a, 1995b, 1995c; Dillon et al., 1995). Rho is a member of the Rho/Rac family (RhoA, RhoB, RhoC, Rac 1, Rac 2, and CDC42) of low molecular weight guanosine 5' triphosphate (GTP)-binding proteins that are involved in the regulation of the cellular cytoskeletal system. Each toxin is capable of transferring glucose from uridine diphosphate glucose to Rho. When this occurs, the ability of Rho to be involved in the dynamic equilibrium of soluble to insoluble actin is impaired. The disruption of the cellular cytoskeleton most likely results in the cell rounding and eventual cell death observed with these toxins. Other members of the large clostridial cytotoxin group also share this ability, although C. sordellii toxin LT monoglucosylate members of the Ras subfamily and α-toxin from C. novyi use UDP-GlcNAc rather than UDP-Glc as the substrate (Von Eichel-Streiber et al., 1996). The glucosyltransferase domain resides within the first 546 amino acids of the toxins (Hofmann et al., 1997; Wagenknecht-Wiesner et al., 1997). The location of the domain has been demonstrated by the microinjection of a 63-kDa recombinant fragment of toxin B into NIH-3T3 cells, which caused the cells to round identically to cells treated with holotoxin. In addition to the inactivation of Rho, other possible mechanisms of toxin A may be its ability to damage mitochondria and activate other pathways such as p38 MAP kinase pathway. Toxin A also may increase the expression of certain cytokines (e.g, IL-8) independent of its effect on Rho (Liu et al., 2003).

ATYPICAL TOXIGENIC STRAINS Within the group of toxigenic C. difficile, there are several distinct toxin phenotypes: A+/B+, A–/B+, and A+/B–. Typical A+/B+ isolates are by far the most prevalent. Typical isolates produce toxin A and toxin B. The toxins appear to be coordinately regulated since strains produce either high, intermediate or low levels of each toxin. Within this group, strains may vary by more than 100,000-fold in the amount of toxin produced in vitro. Typical toxigenic isolates probably account for 95% or more of the cases of C. difficile disease. Atypical A–/B+ isolates, which have only recently been described, comprise 5% or less of the clinical isolates. Atypical isolates produce only toxin B. The A–/B+ isolates carry a full-length toxB gene but only a truncated toxA gene. In addition, the truncated toxA gene has a stop codon located close to the 5' end of the gene. Atypical A–/B+ isolates can cause disease and death even though they do not produce toxin A. Toxin B from atypical A–/B+ isolates crossreacts extensively with toxin B from typical strains. However, the atypical toxin B is approximately tenfold more cytotoxic and lethal. In addition, it mimics C. sordellii toxin LT in that it monoglucosylates a broader range of G-proteins, possibly explaining the increased toxicity. Only a single A+/B– isolate has been reported, and it was isolated from a horse.

IOTA TOXIN Some strains of C. difficile produce τ toxin, which is a binary ADP-ribosylating toxin that modifies actin (Perelle et al., 1997; Braun et al., 2000; Gulke, 2001). The toxin is composed of a 48-kDa enzymatic component (referred to as "CDTa") and a 94-kDa binding component (referred to as "CDTb"). These two components are not covalently linked. Within CDTa, the N-terminal portion interacts with CDTb, and the C-terminal portion carries out the enzymatic activity (Stubbs et al., 2000). The τ toxin is a member of the class of binary ADP-ribosylating toxins that include τ toxin from C. spiroforme and C. perfringens. The τ toxin from C. difficile, C. spiroforme and C. perfringens crossreact immunologically, both with the enzymatic component and the binding component. Also included in this group of binary ADP-ribosylating toxins is C2 toxin from C. botulinum. C2 toxin, however, does not crossreact immunologically with any of the τ toxins. Current estimates suggest that the number of strains that carry a functional τ toxin is roughly 12% or less. Epidemiological studies

are under way to determine the prevalence of clinical strains that produce τ toxin and whether there are A–/B– strains that carry the τ toxin gene. The τ toxin has only been associated with a few toxinotypes (Rupnik, 2002; see Epidemiology). Currently, the role of τ toxin in *C. difficile* pathogenesis is unknown.

Epidemiology

Epidemiology studies continue to be performed on *C. difficile* primarily because outbreaks are a major problem. The disease does not occur because of antibiotic-resistant isolates. *Clostridium difficile* is sensitive to the antibiotics that cause the disease. Rather, the organism begins to grow as the level of antibiotic in the intestine decreases.

Current estimates indicate that approximately 300,000 cases of *C. difficile* disease occur annually in the United States, and there is no indication that the incidence rates are decreasing. The disease is especially problematic in hospitals with large populations of elderly adults (e.g., Veterans Adminstration hospitals), but it has been reported at all levels of healthcare facilities. It is important that healthcare personnel become familiar with general knowledge about *C. difficile*, its role as a hospital-acquired pathogen, and the fact that it is spread most commonly by hospital personnel.

A variety of methods, including plasmid and bacteriocin typing, bacteriophage typing, electrophoretic profiles, and serotyping, have been used to study isolates from outbreaks. Bacteriophage, plasmid and bacteriocin typing are restrictive because only about 75% or less of the isolates can be typed. More recently, restriction endonuclease mapping has been used effectively to identify and group clinical isolates. All of these methods have provided evidence that outbreaks are due to in-house strains and that strains are spread effectively from patient-to-patient through contact with healthcare workers. Clinical isolates can be obtained not only from the patient, but also from linens, curtains and furniture in the infected patient's room. Spores of the isolate can persist for months to years, further complicating any efforts to decontaminate the room and minimize dissemination of the organism.

Asymptomatic carriage of toxigenic *C. difficile* occurs at a rate probably higher than most medical professionals realize. In one study, 21% of the patients who were negative when entering the hospital became positive while hospitalized (McFarland et al., 1990). The majority of these (63%) remained asymptomatic even though most received antibiotics. Patients that become asymptomatic carriers tend to have low or unde-tectable levels of toxin but high numbers of the organism. The reasons for this are unclear, but asymptomatic carriers can spread their isolates to other patients, who then develop *C. difficile* disease. In general, procedures for identifying carriers and limiting the risk factors associated with carriers are not implemented at most institutions. In most instances, any efforts to identify carriers are limited by costs and risk analysis. Carriers may be a primary risk factor for elderly patients who are transferred to long-term care facilities, and in some instances, transfers to these facilities have been denied because of asymptomatic carriage status.

Many infants (50% or higher in some studies) carry toxigenic *C. difficile* in their intestines but do not develop any signs of clinical illness. The resistance of infants to *C. difficile* disease has been recognized for some time (since the early 1980s), but there still is no clear understanding of the mechanism of protection. It appears that colonization by infants is due to environmental strains, and that isolates from infants can be spread through hospital wards. In addition, there have been several instances in which the isolates shed by the infant caused AAD in mothers treated with antibiotics after birth (McFarland et al., 1998). There also have been reports of infants who appear to develop a true case of *C. difficile* disease (Tvede et al., 1990; Kader et al., 1998). In these instances, the infants had some predisposing factors (premature birth, sepsis requiring antibiotics, etc.) that affected the integrity of the mucosa and mucosal microflora. Thus, on rare occasions, infants can develop the disease, but in general, *C. difficile* disease in infants is very uncommon.

Nontoxigenic strains form spores and are spread through hospitals similarly to toxigenic strains. On occasion, patients can be co-infected with multiple strains, including both a nontoxigenic and toxigenic strain. For this reason, it is important to confirm the presence of a toxigenic strain because nontoxigenic strains do not cause disease. Patients colonized with nontoxigenic strains do not need to be treated for *C. difficile* disease. In fact, nontoxigenic strains may be protective by competing with toxigenic strains for available nutrients (Borriello and Barclay, 1985b). For this reason, if bacterial culture is used as a diagnostic aid, multiple colonies should be selected and evaluated for toxin production.

The results of a number of studies based on serotyping suggest that certain strains of *C. difficile* are associated with particular target populations. For example, in some institutions, serogroups associated with elderly adults have been shown to be distinct from those associated with infants. This has been of interest because of the resistance of infants to *C. difficile* disease.

Several studies from the early 1980s indicate the association of a particular strain of *C. difficile* with cystic fibrosis patients in the absence of any disease. However, no follow up studies have appeared. In addition, a particular serogroup has been associated more closely with acquired immunodeficiency syndrome (AIDS) patients. In this instance, it was suggested that the strains, which were more resistant to tetracycline, chloramphenicol, erythromycin, rifampin, and clindamycin than other strains, were more closely associated with AIDS patients because these patients were on multiple antibiotic therapy. The interpretation of results describing the association of specific isolates and patient groups is complex. Many of these studies involved isolates from the same or close facilities, suggesting that in some instances, the close association of strain to patient group resulted from the spread of an in-house strain.

Most recently, efforts to characterize groups of A+/B+ and A–/B+ isolates have centered on toxinotyping utilizing PCR and restriction analyses of the pathogenicity locus. The characterization studies have been performed on *C. difficile* collections in Belgium, Wales, Japan, Korea and Indonesia (Rupnik et al., 1997; Rupnik et al., 1998; Rupnik et al., 2003). On the basis of distinct deletions in different portions of the *toxA* and *toxB* genes, as well as insertions in other portions of the pathogenicity locus, at least 20 toxinotypes (designated "toxinotypes I–XX") have been identified. The prevalence of these isolates varies from hospital to hospital and from country to country. Most of the isolates fall into the A+/B+ category, but within this group, there are variant toxinotypes. New findings suggest that the A–/B+ group, which originally appeared to be primarily a coherent group, is comprised of variant toxinotypes as well. Recently, a pathogenic clinical isolate was identified that produces a variant toxin B (with broad substrate specificity for G-proteins) but which also produces a functional toxin A (Mehlig et al., 2001).

Clinical Illness

DISEASE *Clostridium difficile* is an excellent example of a classic opportunistic pathogen. In healthy persons, the intestinal flora is highly protective against infection by intestinal pathogens. However, when this protective flora is disrupted, most typically by antibiotics or other powerful drugs such as the anticancer agents, *C. difficile* is able to enter and colonize the colon. The organism begins to grow as the amount of antibiotic in the colon drops below the level that inhibits its growth. This occurs with toxigenic and nontoxigenic isolates, both of which form spores and are present in the environment. Patients that are colonized with *C. difficile* will have counts of >10^8 per gram in their feces. Although it has been suggested that the organism attaches to gut receptors, it is more likely that the organism grows throughout the lumen. As the organism grows in the colon, it begins to release toxin through autolysis as it reaches stationary phase. The toxins, particularly toxin A, likely target galactose-containing receptors once they are produced in the colon. Toxin A then is taken up through receptor-mediated endocytosis and generalized pinocytosis. Once in the cell, the toxic activity is expressed through the monoglucosylation of the GTP-binding protein Rho, resulting in a shutdown of the cytoskeletal system and cell rounding, and eventually cell death. In addition to its direct toxic action, toxin A likely is chemotactic, resulting in an intense inflammatory response (Triadafilopoulos et al., 1987; Triadafilopoulos et al., 1989; Pothoulakis et al., 1988). Other mechanisms may include the ability of toxin A to damage internal cellular organelles and activate other pathways that are independent of Rho inactivation (Liu et al., 2003). Inflammation also is triggered by the tissue damage caused by toxin A. The disruption of the mucosal membrane through direct toxic action and inflammation maintains the disruption of the microflora, resulting in further exacerbation of the disease.

The role of toxin B in the disease process is less understood than that of toxin A. Toxin B from typical A+/B+ isolates does not have any significant activity in the intestine of experimental animals. However, toxin B mixed with low nontoxic amounts of toxin A is lethal when given intragastrically to animals. In addition, toxin B is lethal when given to animals in which the mucosa has been damaged (Lyerly et al., 1985). These observations indicate a synergistic action between the toxins. Further, in immunodeficient mice containing transplanted human intestinal xenografts, toxin B causes intestinal permeability and severe inflammation (Savidge et al., 2003). In patients infected with atypical A–/B+ isolates, these observations suggest that toxin B may be capable of causing the tissue damage associated with the disease. However, the tissue damage may also result from the more extensive toxic properties of toxin B from A–/B+ isolates. This possibility is based on findings showing that when compared to toxin B from typical A+/B+ isolates, toxin B from A–/B+ isolates is 1) almost tenfold more lethal, 2) enterotoxic in animal models, and 3) targets a broader array of G-proteins (Rho, Rac and Ras for atypical toxin B versus just Rho for typical toxin B). In this regard, the atypical toxin B more closely resembles *C. sordellii* lethal toxin.

These differences may explain the ability of atypical isolates to cause disease in the absence of toxin A.

The clinical criteria for *C. difficile* disease has been defined as diarrhea in which no other cause has been established, loose or unformed stool that takes the shape of the container, three or more bowel movements per day, duration of at least 2 days, and a history of antibiotic or antineoplastic agents in the preceding 4–6 weeks (Gerding and Brazier, 1993). Patients do not typically develop abdominal pain, fever, ileus or constipation. The presence of toxin is strongly supportive of *C. difficile* disease. Metronidazole or vancomycin is typically used to treat the disease, and a positive response to these antibiotics often is considered confirmatory for *C. difficile* disease. However, these antibiotics are not specific for *C. difficile* and will act on other intestinal pathogens that may cause AAD.

Pseudomembranous colitis, the severe stage of the disease, is not observed as frequently as it was 20 years ago because of more accurate rapid diagnostic testing, greater awareness of the disease, and quicker implementation of therapy. The condition, however, still occurs and may develop following the onset of diarrhea, occasional fever and chills, and some bleeding. The pseudomembrane lesions are typically several millimeters in diameter and appear as small whitish yellow plaques along the mucosal wall. The presence of these plaques, which are composed of necrotic cells, debris, and leukocytes, is diagnostic for PMC. Inflammation probably plays a primary role in the onset of these lesions. In severe *C. difficile* disease, there is an intense inflammatory component, due in part to the tissue damage from the toxin activity and from the chemotactic properties of toxin A. *Clostridium difficile* disease is most commonly manifested as antibiotic-associated diarrhea. Of the fecal specimens submitted to the laboratory for *C. difficile* testing, 5–15% usually are positive, although a positivity rate of up to 25% may be observed during outbreaks. Although clinical isolates differ in the amount of toxin they produce in vitro, no correlation has been established between levels of in vitro toxin production and severity of disease.

Clostridium difficile disease most often is treated with oral metronidazole or vancomycin. In most instances, the therapy is effective, although relapse rates of up to 20% have been noted. Relapses generally occur within several weeks of remission, probably from residual spores that remain in the patient. On occasion, relapses can occur following infection with a different isolate. Relapses do not occur, as some have suggested, because of the development of resistant strains. Rather, they occur because the

normal flora has not become reestablished, and the colon still is vulnerable to infection. Relapses can occur multiple times, and different therapeutic approaches, including limited antibiotic therapy and probiotics have been used with some success.

Several studies have demonstrated the presence of *C. difficile* and its toxins in patients with ulcerative colitis or Crohn's disease. Therefore, patients with inflammatory bowel disease who do not respond to therapy should be screened for *C. difficile* toxin, especially if they have undergone recent antibiotic therapy (Greenfield et al., 1983; Keighley et al., 1982).

DIAGNOSIS The detection of pseudomembranes by endoscopic exam using procedures such as rigid proctoscopy, flexible sigmoidoscopy, or surgical exploration is considered diagnostic for *C. difficile* disease. Under these conditions, in vitro laboratory tests are used as supplemental tests to confirm the diagnosis. Endoscopic examination is not performed routinely in persons with antibiotic-associated diarrhea.

Bacterial culture, tissue culture assay, and detection of a nontoxic antigen or toxins A and B with antibody-based tests are used as in vitro diagnostic aids for *C. difficile* disease (Table 4). Bacterial culture is the most complicated of these tests, and it seldom is used because it is tedious, time-consuming, and inconsistent. The procedure requires expertise with anaerobic bacteriology, and the media must be high quality to ensure high recovery rates. Cefoxitin-cycloserine-fructose agar (CCFA) is the media of choice for this procedure, although some laboratories use selective broth media (e.g., brain heart infusion broth supplemented with cefoxitin and cycloserine). *Clostridium difficile* is not as strict an anaerobe as some other clostridia (e.g., *C. tetani*), but precautions (e.g., good technique, high quality media, fresh stool specimens, etc.) should be taken for higher recovery rates. Not all isolates of *C. difficile* sporulate to the same degree. However, in many instances, heat-shock or alcohol wash procedures can be used to improve recovery. *Clostridium difficile* gives flat rough colonies that grow to several millimeters in diameter, and colonies can be presumptively identified on CCFA. Other anaerobes, as well as nontoxigenic isolates of *C. difficile*, grow on CCFA. It has been our experience that roughly 25% of *C. difficile* isolates from patients with antibiotic-associated diarrhea are nontoxigenic. For this reason, presumptive colonies should be screened further for toxin production.

A number of *C. difficile* antigen tests are on the market. The antigen is glutamate dehydrogenase, a metabolic enzyme produced both by toxigenic and nontoxigenic isolates (Lyerly et al.,

Table 4. Methods and tests to detect *C. difficile* and its toxins.

Method	Entity detected	Advantages	Limitations	Available tests (and sources)
Bacterial culture	Organism	Most sensitive, specific	Efficiency varies from lab to lab, use of a stereomicroscope recommended	CCFA with horse blood preferred; 500μg of cycloserine and prereduction of medium increases the isolation rate of *C. difficile* (Remel, Lenexa, KS)
Latex agglutination	Glutamate dehydrogenase	Rapid, simple	Not extremely sensitive, does not distinguish between toxigenic and nontoxigenic strains of *C. difficile*	CDT (Becton Dickinson Microbiology Systems, Sparks, MD) Meritec *C. difficile* (Meridian Diagnostics Inc., Cincinnati, OH)
Membrane EIA	Glutamate dehydrogenase	Rapid, simple	More sensitive than latex agglutination, does not distinguish between tox+ and tox– strains	ImmunoCard *C. difficile* (Meridian Diagnostics, Inc., Cincinnati, OH) Triage *C. difficile* panel (Biosite Diagnostics, Inc., San Diego, CA)
Microwell EIA	Glutamate dehydrogenase	Rapid, simple, specific	More sensitive than latex agglutination, does not distinguish between tox+ and tox– strains	C. diff CHEK-30 (TechLab, Inc., Blacksburg, VA) C. diff CHEK-60 (TechLab, Inc., Blacksburg, VA)
Tissue culture	Toxin B	Sensitive, specific	Most assays require 24–48h to complete; toxin B can be inactivated, resulting in false-negative results	*C. difficile* Toxin/Antitoxin (TechLab, Inc., Blacksburg, VA) *C. difficile* Tox-B Test (Wampole Laboratories, Cranburry, NJ and TechLab Inc., Blacksburg, VA) *C. difficile* Toxititer (Bartels, Inc., Issaquah, WA) Cytoxi (Advanced Clinical Diagnostics, Toledo, OH)
Microwell EIA	Toxin A	Rapid, simple, specific	Some kits have higher sensitivity than others, some kits may yield indeterminant readings. Does not detect atypical A–/B+ isolates that cause disease	CD-Tox (Porton, Cambridge, England) Premier (Meridian Diagnostics, Inc., Cincinnati, OH) Prospect II C. difficile Toxin A microplate (Alexon-Trend, Sunnyvale, CA)*C. difficile* TOX-A TEST (Wampole Laboratories, Cranburry, NJ and TechLab, Inc., Blacksburg, VA) Toxin A EIA (Bartels, Inc., Issaquah, WA) Toxin CD Test (Becton Dickinson Microbiology Systems, Sparks, MD) VIDAS-CDA (bioMerieux Vitek, Hazelwood, MO) Triage C. difficile panel (Biosite Diagnostics, Inc., San Diego, CA)*C. difficile* Toxin A Microplate Assay (Remel, Lenexa, KS)
Membrane EIA	Toxin A	Rapid	Not as sensitive as microwell EIAs	*C. difficile* Toxin A (Oxoid, Inc., Ogdensburg, NY) Triage *C. difficile* Panel (Biosite Diagnostics, Inc., San Diego, CA)
OIA	Toxin A	Rapid, simple	Less sensitive than EIA	CdTOX A OIA (ThermoBiostar, Boulder, CO)
Microwell EIA	Toxins A and B	Rapid, simple, specific	Some kits have higher sensitivity than others, some kits may yield indeterminant readings	*C. difficile* TOX A/B II (Wampole Laboratories, Cranburry, NJ and TechLab, Inc., Blacksburg, VA) Cd Toxin A + B (Rohm Pharma, Darmstadt, Germany) Premier A + B (Meridian Diagnostics, Inc., Cincinnati, OH)

Abbreviations: CCFA, cycloserine-cefoxitin-fructose agar; EIA, enzyme immunoassay; and OIA, optical immunoassay.

1991). The newer membrane and microwell EIA antigen tests that are available are more sensitive than the latex formats that appeared on the market more than ten years ago (Lee et al., 2003). Because of their higher sensitivity, the newer tests have excellent negative predictive values and accurately rule specimens negative for *C. difficile*. For laboratories that perform tissue culture assays, these tests are valuable as screens to reduce the amount of diagnostic testing by tissue culture. Tissue culture assays are more tedious than the membrane and microwell EIAs and require 48 hours before ruling a specimen negative, compared to an hour or less for the antigen tests. For laboratories that perform EIA for toxin, the antigen tests can be used to identify patients who may have all the symptoms and conditions for *C. difficile* AAD, but who have only trace amounts of toxin owing to low expression or inactivation, and who are negative or borderline in toxin EIAs. The glutamate dehydrogenase (GDH) antigen is produced in much higher amounts than either toxin A or toxin B, and a positive test may alert the physician to monitor the patient and perform additional toxin testing if needed.

Diagnostic tests that detect toxin are highly suitable for confirming the presence of toxigenic isolates in a patient. Tissue culture assay and toxin-specific EIAs are available for this purpose. Tissue culture assays are considered to be the gold standard because of the high level of sensitivity. However, on occasion, fecal specimens cause cell rounding and cell stretching owing to factors other than toxins A and B (Lyerly et al., 1998). Therefore, tissue culture results should not be overinterpreted with specimens that cause cell stretching or rounding not neutralized by specific *C. difficile* antitoxin. The tissue culture assay has some disadvantages. It is tedious, results cannot be ruled negative for 48 h, and in-house methods often are not standardized. Cell lines that are commonly used include human foreskin, WI-38 lung fibroblasts, and CHO cells. A cutoff of 50–90% cell rounding is recommended in most tests, although some laboratories consider any cell rounding to be positive. Weakly positive specimens should be interpreted cautiously since freezing the specimen or extended storage conditions (>72 h) may lead to weak cytotoxic activity.

A large number of toxin-specific EIAs are available. Most detect toxin A, although several detect both toxin A and toxin B. Until recently, ELISAs that detect both toxin A and toxin B were believed to be unnecessary. Toxin A had been shown to be a very potent enterotoxin in experimental animal models, and it was an excellent diagnostic marker for toxigenic *C. difficile* in fecal specimens. In addition, there was some

question about the role of A–/B+ isolates in clinical disease. Until recently, only one A–/B+ isolate, CCUG 8864, had been described (Torres, 1991; Lyerly et al., 1992; Wilkins and Lyerly, 2003). Interestingly, though, toxin B from the 8864 isolate was more enterotoxic than toxin B from typical A+/B+ isolates. The appearance of true A–/B+ isolates from clinical specimens soon became apparent by testing specimens with a panel of tests that detected both toxins. These atypical isolates now have been identified in Japan, England, Canada, Israel, the Netherlands, France, and the United States. In Japan, most of the A–/B+ isolates have been associated with asymptomatic persons or only with mild diarrhea (Kato et al., 1998). In Canada, the United States and Europe, however, several deaths and outbreaks have been attributed to A–/B+ isolates (Lyerly et al., 1998; Alfa et al., 2000; Johnson et al., 2001; Kuijper et al., 2001; Pituch et al., 2001; Barbut et al., 2002; Limaye et al., 2002). In parts of Europe, approximately 5% of the clinical *C. difficile* isolates are A–/B+, and they occur in roughly 25% of the hospitals that have been surveyed. In general, the clinical significance of A–/B+ isolates can be summarized as follows: 1) A–/B+ isolates may cause disease that can be severe or fatal if not promptly diagnosed and treated; 2) the incidence of A–/B+ isolates appears to be low; 3) A–/B+ isolates are spread similarly to typical A+/B+ isolates, and 4) A–/B+ isolates do not react in toxin A-specific EIAs. They do react in EIAs that detect both toxins, are positive in tissue culture assays, and react in antigen tests. Atypical A–/B+ isolates do not react in toxin A-specific EIAs because they 1) carry a truncated *toxA* gene that lacks the portion of the toxin recognized by the antibodies used in the toxin A-specific ELISAs (Kato et al., 1999; Moncrief et al., 2000b), and 2) there is a stop codon located near the 5'-end of the truncated gene (Von Eichel-Streiber et al., 1999).

PCR for the amplification of the *toxA* and *toxB* genes has been proposed as an alternative to tissue culture and antibody-based assays for detecting toxigenic *C. difficile* in fecal specimens. In most of the studies, direct amplification using specific toxin gene primers resulted in a highly specific product that identified toxigenic *C. difficile* and did not detect *C. sordellii*, which produces crossreacting toxins (Kato et al., 1993; Gumerlock et al., 1993; Kuhl et al., 1993; Alonso et al., 1997; Karasawa et al., 1999). The correlation between tissue culture assay was >98%. There are PCR-inhibitory factors in stool specimens, and clean-up steps prior to amplification do improve performance. As an alternative, magnetic beads coated with monoclonal antibodies specific for *C. difficile*, but which crossreact with *C. sordellii* and *C. bifermentans*, have been used

as a capture and enrichment step, followed by PCR specific for *toxB* (Wolfhagen et al., 1994). In more recent studies, the reported sensitivity for PCR amplification of *toxB* when compared to tissue culture was 92% (Guilbault et al., 2002). When targeting *toxA* and *toxB* and using a real-time fluorescence-based multiplex PCR assay, the reported sensitivity was 97% (Belanger et al., 2002). For diagnostic purposes, if PCR testing is to be used, a positive result in the absence of any other test results must be interpreted cautiously. Many patients carry toxigenic isolates asymptomatically or they may have diarrhea due to causes other than *C. difficile*.

Treatment

As an initial step in the treatment of *C. difficile* disease, the causative antibiotic should be discontinued. In some instances, simply stopping the antibiotic has led to recoveries in 25–30% of patients with AAD. By stopping the offending antibiotic, the normal microflora begins to become reestablished, helping the intestine to recover. The most commonly used antibiotics for *C. difficile* are metronidazole and vancomycin, both requiring a 7–10 day course of therapy. Metronidazole is the preferred oral agent of therapy (Fekety, 1997; MacLaren et al., 1997; Reinke, 1998; Wilcox, 1998). Metronidazole, which is selectively toxic for anaerobic organisms and some microaerophiles, acts as an electron acceptor and causes biochemical lesions in the cell structure. In addition, metronidazole interferes with DNA synthesis in anaerobes. In the body, metronidazole is metabolized to the intermediate hydroxymetronidazole, which has a minimal inhibitory concentration (MIC) of 0.5–4.0 μg/ml, compared to 0.25–1.00 μg/ml for the parent compound (Bolton and Culshaw, 1986). Metronidazole is considerably cheaper than vancomycin, and it has been used more extensively for treating patients who have mild or moderate disease. Typically, oral doses of 250–500 mg four times daily is given.

Vancomycin, which inhibits cell wall synthesis by binding to precursors of the cell wall (perhaps D-alanylalanine), is highly bactericidal for *C. difficile*. This drug is not absorbed very well in the intestine, and high concentrations are achieved when it is administered orally. The typical dose range is 125–500 mg at 6-hour intervals, giving fecal levels in excess of 1 mg/ml, well above the MIC value for *C. difficile*. The higher dose should be reserved for patients who are critically ill (Fekety et al., 1989). Vancomycin is available in liquid and capsule form, both of which are highly effective. A primary concern is the overuse of vancomycin, leading to the development of vancomycin-resistant enterococci. For this reason,

and because of the high costs of vancomycin, metronidazole probably is used more often for *C. difficile* infections.

Other antibiotics shown to be efficacioius for treating *C. difficile* infections include bacitracin, teicoplanin, and fusidic acid, although these have not been used routinely for this purpose. Other approaches include the use of resins such as cholestyramine or colestipol that bind the toxins of *C. difficile*. The binding resins also have been used in combination with antibiotics to treat patients who relapse. Probiotics such as *Saccharomyces boulardii* and *Lactobacillus* have been used to treat patients with recurrent *C. difficile* disease. *Saccharomyces boulardii* is a nonpathogenic yeast that has been used for years in Europe as a probiotic for persons with intestinal illnesses. Some patients treated with *S. boulardii* show a decrease in the number of CFU and concomitant decrease in toxin levels, followed by clinical improvement within days to weeks. *Lactobacillus* GG, a human isolate, has been used in some patients with limited success. Fecal enemas, which are not used in the United States, and combinations of various intestinal bacteria, including *Streptococcus*, *Clostridium*, *Bacteroides* and nontoxigenic *C. difficile*, have been suggested as possible alternatives to the use of antibiotics as therapeutics. These studies are ongoing and results are mixed, but they present possible ways in which the normal flora is allowed to reestablish itself. In addition to antibiotics and probiotics, another therapeutic approach includes the oral administration of bovine gamma globulin against *C. difficile*. In studies performed by us and other researchers, hamsters were protected against challenge with toxigenic *C. difficile* when treated prophylactically with gamma globulin against the organism and its toxins. In human volunteers, results have shown that bovine gamma globulin administered orally retained its neutralizing activity against toxin A in the intestine (Warny et al., 1999). Therefore, it has been suggested that oral administration of gamma globulin against *C. difficile* may be particularly effective in high-risk populations such as those in Veterans Administration hospitals. For relapsing patients, combinations of no antibiotic therapy, an additional round of antibiotic therapy, and alternative treatments such as toxin-binding resins and probiotics (*Saccharomyces*, *Lactobacillus*, and fecal enemas) have been utilized (Bartlett, 1995).

An awareness of *C. difficile* disease and education of healthcare personnel about methods to reduce the incidence of infections represents an important step in reducing outbreaks of this disease. Measures that help reduce the incidence include 1) proper handwashing and the use of gloves, 2) disinfectants such as hypochlorite to

help reduce spores, 3) avoiding the overuse of antibiotics, and 4) accurate diagnosis and enteric isolation if possible (Barbut and Petit, 2001). Continued surveillance to identify increased incidence also helps to minimize possible outbreaks. Treatment of asymptomatic carriers is not recommended.

Important Points for Healthcare Professionals

For healthcare professionals, we believe the following points are especially relevant:

1) *Clostridium difficile* is the major cause of hospital-acquired diarrhea and colitis. 2) There is no indication that the incidence of *C. difficile* disease is decreasing. *Clostridium difficile* continues to cause outbreaks in hospitals and medical centers around the world. 3) This pathogen is spread from patient to patient by healthcare professionals. 4) The disease does not result from antibiotic-resistant isolates. *Clostridium difficile* is sensitive to the antibiotics that are associated with the disease and only begins to grow as the level of antibiotic in the intestine decreases. 5) Atypical A–/B+ isolates exist and cause disease in humans. For this reason, an ELISA that detects both toxins, or a tissue culture assay for toxin B, should be used as an in vitro diagnostic aid to confirm the presence of *C. difficile* toxin in fecal specimens. 6) Nontoxigenic isolates exist in hospitals and are spread in patient wards. For this reason, antigen tests should be confirmed with toxin tests. 7) Many patients become asymptomatic carriers of *C. difficile* after entering hospitals and being placed on antibiotic therapy. It is not understood why some persons become ill, whereas others remain asymptomatic. Identification and treatment of asymptomatic carriers is not recommended. 8) An awareness of *C. difficile* disease and education about methods to reduce the incidence represents an important step in reducing outbreaks of the disease.

CHAPTER 1.2.23

Clostridium perfringens and Histotoxic Disease

JULIAN I. ROOD

Introduction

The clostridia are a diverse group of Gram-positive spore-forming bacteria that cause a variety of potentially fatal human diseases including gas gangrene, tetanus, botulism and pseudomembranous colitis. The common feature of all of these diseases is that spore formation is important in their epidemiology and that they are mediated by powerful protein toxins. Since these syndromes are best discussed on a systems-related basis, rather than by their causative bacterial species, the clostridial chapters have been divided into separate discussions on the neurotoxic (Neurotoxigenic Clostridia in this Volume), enterotoxic (The Enterotoxic Clostridia in this Volume) and histotoxic clostridia. For earlier reviews on these topics see Rood et al. (1997) and Fischetti et al. (2000). The reader is also referred to McLennan's classical review of histotoxic clostridial infections of man (MacLennan, 1962) and a more recent review of clostridial diseases of animals (Songer, 1996). The emphasis of this chapter, and those associated with it, will be on the pathogenesis of these clostridial diseases and the structure and function of the toxins. This chapter will focus on clostridial myonecrosis, or gas gangrene, caused by *Clostridium perfringens*. It will also include a discussion of the genetics and genomic analysis of this organism, which is the most intensively studied clostridial species.

Phylogeny

The clostridia are a very heterogenous group of bacteria that were originally classified in the same genus because they were Gram-positive rods that had the ability to form heat-resistant endospores and grew only under anaerobic conditions. The genus is now much more diverse and includes Gram-negatives, non-spore-formers and aerobes. Therefore, taxonomically the clostridia are much more disparate than most bacterial genera: if it wasn't for their medical significance, they would be broken up into many different genera. On the basis of their 16S rRNA sequences, they can be divided into 19 clusters that are intermingled with members of other genera (Collins et al., 1994; Stackebrandt et al., 1999). *C. perfringens*, along with *C. septicum* and *C. novyi,* as well as *C. botulinum* and *C. tetani*, belongs to cluster I, which also includes the type strain *C. butyricum* (Fig. 1). By contrast, *C. difficile* and *C. sordellii* belong to cluster XI. Even within species there is considerable taxonomic confusion. For example, 16S rDNA sequence analysis indicates that *C. novyi* types B and C and *C. histolyticum* probably represent a single species that is more closely related to *C. botulinum* types C and D than to *C. novyi* type A (Sasaki et al., 2001a). Subsequent phylogenetic analysis of the flagellin gene *fliC* indicates that *C. novyi* type B and *C. histolyticum* can be differentiated from one another (Sasaki et al., 2002).

It is time for the phylogenetic reclassification of the clostridia, but this process would present considerable difficulty for medical microbiologists, with *C. botulinum* types C, D and E having to be named as a different species. At the furthest extreme, if taxonomic rules were to be strictly enforced, the cluster I clostridia, including the type strain, would have to be moved to the genus *Sarcina*. Even if the genus *Clostridium* was to be retained and restricted to cluster I and II species, which is possible, then pathogens such as *C. difficile* and *C. sordellii* would still have to be given new genus names (Stackebrandt and Rainey, 1997). Clearly, the reclassification of the clostridia, although essential, is not going to be a simple task.

Genetics

The genetics of *C. perfringens* is highly developed, with conjugation and transformation methods well established. Several plasmids and mobile genetic elements have been identified and analyzed in considerable depth, and it is possible to genetically manipulate at least two
Fig. 1. Phylogenetic relationships of clostridial species within 16S rDNA cluster I. Pathogenic species are shown in bold. The bar represents 10% sequence divergence. From Stackebrandt et al. (1999), with permission.

strains of *C. perfringens* and to construct chromosomal mutants by homologous recombination (Lyras and Rood, 2000a).

Clostridium perfringens Plasmids

THE BACTERIOCIN PLASMID pIP404 AND CLONING VECTORS BASED ON pIP404. The 10,207-bp mobilizable plasmid pIP404 encodes 10 open reading frames (ORFs) and was the first *C. perfringens* plasmid to be completely sequenced (Garnier and Cole, 1988a). The *bcn* gene, which encodes the secreted bacteriocin BCN5, and the *uviAB* operon are both positively regulated at the transcriptional level by exposure to ultraviolet light (Garnier and Cole, 1988c). Although it was originally suggested that UviA may be involved in bacteriocin immunity, the UviA protein has sequence similarity to the transcriptional regulators BotR from *C. botulinum* (Marvaud et al., 1998a), TetR from *C. tetani*

(Marvaud et al., 1998b), and TxeR from *C. difficile* (Mani and Dupuy, 2001), which positively regulate botulinum toxin, tetanus toxin, and the *C. difficile* toxins A and B production, respectively. TxeR has been shown to be an alternative sigma factor that activates transcription of its target genes by binding to the RNA polymerase core enzyme and promoting its binding to a specific promoter target site (Mani and Dupuy, 2001; Mani et al., 2002). BotR and TetR are functionally interchangeable, and it is highly likely that the same would apply to TxeR and UviA. That is, these proteins are likely to form a functionally similar group of alternative sigma factors.

UviB is a potential cell membrane protein and may play a role in bacteriocin secretion (Garnier and Cole, 1988a). The *cop* gene encodes a putative membrane protein that is involved in copy number control (Garnier and Cole, 1988b). Similarly, plasmid replication is known to be dependent upon the basic protein product of the *rep*

gene (Garnier and Cole, 1988b). The minimal replication region of pIP404 comprises the *rep* gene and the region of repeated sequences that are immediately upstream. The plasmid also carries a *res* gene, which encodes a protein that belongs to the resolvase family of site-specific serine recombinases and is probably involved in the resolution of plasmid multimers (Garnier et al., 1987; Garnier and Cole, 1988a). Although the function of ORF10 is not known, there is a chromosomal variant located upstream of the regulatory *virRS* operon (Lyristis et al., 1994). Since these proteins have an N-terminal internal *N*-acetylmuramyl-L-alanine amidase domain (COG0860), ORF10 could be involved in the release of bacteriocin or other proteins from the cell. The role of the other three pIP404-encoded genes, ORFs 6, 7 and 9, is unknown.

Initial studies on the replication of pIP404 were carried out in *Bacillus subtilis* (Garnier and Cole, 1988b). However, with the advent of methods for the transformation of *C. perfringens* cells by electroporation (Allen and Blaschek, 1988; Scott and Rood, 1989), pIP404 was rapidly utilized for the construction of shuttle vectors (Sloan et al., 1992; Bannam and Rood, 1993). The most commonly used *Escherichia coli-C. perfringens* shuttle plasmids are those derived from pJIR418. This plasmid contains the ColE1-like replication region, multiple cloning sites, and *lacZ'* gene from pUC18, the *rep* gene and associated *C. perfringens* origin of replication from pIP404, and the *C. perfringens catP* and *erm*(B) genes, which encode resistance to chloramphenicol and erythromycin, respectively (Sloan et al., 1992). Modified shuttle plasmid derivatives of this plasmid include the deletion derivatives pJIR750, which encode chloramphenicol resistance, and pJIR751, which encodes erythromycin resistance (Bannam and Rood, 1993), the promoter probe vector pPSV (Matsushita et al., 1994), the expression vector pFF (Takamizawa et al., 2004), and the mobilizable shuttle vectors pJIR1456 and pJIR1457 (Lyras and Rood, 1998a). The latter two plasmids contain the *oriT* site from RP4, and as a result they can be used to introduce cloned genes into *C. perfringens* by conjugative mobilization from *E. coli*. Subsequent studies have shown that pJIR1457 can be introduced by conjugative mobilization from *E. coli* into both *C. botulinum* (Bradshaw et al., 1998), *C. difficile* (Mani et al., 2002) and other clostridial species (D. Lyras, M. Awad, and J. Rood, unpublished observation). Derivatives of pJIR418 have also been introduced into *C. paraputrificum* by electroporation (Sakka et al., 2003).

THE pCW3 FAMILY OF CONJUGATIVE TETRACYCLINE RESISTANCE PLASMIDS. Early studies on antibiotic resistance determinants showed that both tetracycline and chloramphenicol resistance genes could be carried on conjugative plasmids (Brefort et al., 1977; Rood et al., 1978). pCW3 is a 47-kb plasmid that carries an unusual tetracycline resistance determinant that consists of an operon containing two distinct tetracycline resistance genes, *tetA*(P) and *tetB*(P) (Sloan et al., 1994). The TetA(P) protein is a transmembrane efflux protein that confers tetracycline resistance by actively effluxing tetracycline from the cell. It is a distant member of the Major Facilitator Superfamily and has been extensively analyzed (Kennan et al., 1997; Bannam and Rood, 1999; Bannam et al., 2004). The TetB(P) protein is related to the Tet(M) protein from Tn*916* and confers tetracycline and minocycline resistance by a ribosomal modification mechanism (Sloan et al., 1994).

Expression of the tetracycline resistance encoded by the *tetA*(P)*tetB*(P) operon on pCW3 is induced by subinhibitory concentrations of tetracycline (Rood, 1983; Abraham and Rood, 1985a) via a complex process that is not well understood but is known to involve a host-encoded factor (Johanesen et al., 2001b). Induction involves transcriptional activation from a promoter located 529 bp upstream of the *tetA*(P) start codon, but no transcriptional activator has been identified (Johanesen et al., 2001a). Unusually, there is a transcriptional terminator located between the *tet*(P) promoter and the start codon, but the role that this terminator plays in the regulation process is not known. We have postulated that its function is to prevent overexpression of the TetA(P) transmembrane protein (Johanesen et al., 2001a).

All of the conjugative tetracycline resistance plasmids that have been analyzed from *C. perfringens*, irrespective of their geographic or host source, are closely related to pCW3 (Abraham and Rood, 1985b; Abraham et al., 1985c). Many of these plasmids are indistinguishable from pCW3 by restriction endonuclease analysis, others have small variations in restriction profile. These data provide good evidence that all conjugative R-plasmids from *C. perfringens* are derived from a single pCW3-like progenitor. Furthermore, the *tetA*(P) gene has been found in other clostridia, often in association with *tetB*(P), providing evidence that pCW3-like plasmids can be transferred to other clostridial species. Note that the *tetB*(P) gene has only been found in association with *tetA*(P) (Sasaki et al., 2001b; Lyras et al., 2004).

pCW3 has now been completely sequenced and shown to have little similarity to other known conjugative plasmids. The 47,263-bp plasmid has a G+C content of 27.6 mol% and encodes 52 putative genes, with only 35% of the predicted gene products having significant

similarity to proteins of known function (T. Bannam and J. Rood, unpublished observation). The region most likely to encode the conjugation-related functions is located in a 12-kb segment that is common to all of the known conjugative tetracycline resistance plasmids from *C. perfringens*. This region is also found in the conjugative enterotoxin plasmid from *C. perfringens* (Brynestad et al., 2001).

The plasmid pIP401 is a conjugative 53-kb plasmid that carries the genes for both tetracycline and chloramphenicol resistance (Brefort et al., 1977). Subsequent studies showed that pIP401 is effectively a derivative of pCW3 that carries the integrative mobilizable element Tn*4451*, which confers chloramphenicol resistance (Abraham and Rood, 1987). Other conjugative tetracycline and chloramphenicol resistance plasmids also consist of pCW3-like plasmids that carry Tn*4451*-like elements (Abraham et al., 1985c; Abraham and Rood, 1987).

THE TOXIN PLASMIDS OF *C. PERFRINGENS*. Traditionally, *C. perfringens* isolates have been divided into five toxin types (A to E), based on their ability to produce four major extracellular toxins (α, β, ε, and ι-toxins; Rood and Cole, 1991), although this classification system is outmoded owing to the identification of other, clinically significant, toxins such as the sporulation-associated enterotoxin, CPE (McClane et al., 2000) and β2-toxin (Gibert et al., 1997). Type A strains are the major human pathogens and, of the toxins used in the typing scheme, only produce α-toxin, which is chromosomally determined. Pulsed-field gel electrophoresis (PFGE) and genomic mapping of *C. perfringens* isolates of various toxin types led to the discovery that the β-, ε- and ι-toxin structural genes are plasmid determined (Canard et al., 1992; Cornillot et al., 1995; Katayama et al., 1996). Therefore, clearly, the toxin typing scheme in effect measures the acquisition of large toxin plasmids by type A strains of *C. perfringens* (Petit et al., 1999). Note that in veterinary and non-foodborne isolates the enterotoxin gene, *cpe*, is also found on a large plasmid, which can be conjugative (Brynestad et al., 2001). Little is known about the genetic organization of any of the large toxin plasmids from *C. perfringens*, although several sequencing projects are well under way.

The Tn*4451* Family of Integrative Mobilizable Elements

As already discussed, early studies led to the identification of pIP401, which carries a chloramphenicol resistance determinant. Conjugative transfer of pIP401 and selection for only tetracycline resistance led to the loss of the chloramphenicol resistance determinant at a high frequency, although some of the transconjugants retained the resistance gene (Brefort et al., 1977). Loss of resistance was associated with loss of a precise 6.2-kb region of DNA, which was subsequently designated as the transposable genetic element "Tn*4451*" (Abraham and Rood, 1987). All of the six chloramphenicol resistance plasmids that have been identified have been shown to carry similar elements (e.g., Tn*4452*), and closely related elements, designated as "Tn*4453a*" and "Tn*4453b*," have been identified on the chromosome of *C. difficile* (Lyras et al., 1998b).

Both Tn*4451* and Tn*4453a* have been sequenced and shown to comprise 6338-bp elements that encode six genes (Bannam et al., 1995; Lyras and Rood, 2000b; Fig. 2). One of these genes, *catP*, confers chloramphenicol resistance by encoding a chloramphenicol acetyltransferase. Although three of the remaining genes, *tnpV*, *tnpY* and *tnpW*, have no known function, *tnpX* is known to be required for excision and insertion of the element (Bannam et al., 1995) and that *tnpZ* encodes a mobilization, or Mob, protein (Crellin and Rood, 1997).

The members of the Tn*4451*/Tn*4453* family are not classical transposons (Adams et al., 2002). They should be more accurately referred to as integrative mobilizable elements (IMEs) because 1) they are excised and inserted by a site-specific recombination process that is encoded by the TnpX protein (Crellin and Rood, 1997; Lyras et al., 2004), which is a serine recombinase not a transposase, and 2) although they are not conjugative, they can be mobilized in the presence of a conjugative plasmid in a specific *oriT*-TnpZ-dependent manner (Crellin and Rood, 1998).

The TnpZ protein is a mobilization protein that has similarity to Mob/Pre mobilization proteins from plasmids from other Gram-positive bacteria (Crellin and Rood, 1998). An *oriT*, or RS$_A$ site is located immediately upstream of the *tnpZ* gene (Fig. 2). TnpZ acts as a DNA relaxase and nicks Tn*4451* at the *oriT* site, and in the presence of the appropriate exogenous conjugation machinery, a single strand of the replicon on which Tn*4451* is located is transferred to a suitable recipient cell. Mutation of either the *tnpZ* gene or the *oriT* site renders the mobilization

Fig. 2. Genetic organization of Tn*4451*. The six Tn*4451* genes are shown by the arrows, with the *oriT* or RSA site indicated by the circle. The directly repeated G$_A$ dinucleotides at the ends of the element are also shown.

system inactive, indicating that both components are required for conjugative mobilization. TnpZ also acts in trans, resulting in the mobilization of plasmids carrying the *oriT* site, even if those plasmids do not carry the *tnpZ* gene (Crellin and Rood, 1998). This mobilization process has been used to develop genetic tools for the analysis of the Tn*4451* insertion and excision process (Lyras et al., 2004).

The excision and insertion of Tn*4451* are catalyzed by TnpX, which is a member of the large resolvase family of site-specific serine recombinases (Smith and Thorpe, 2002). TnpX is an 82-kDa protein that has a functional N-terminal resolvase domain (Crellin and Rood, 1997). Most resolvases are ca. 20-kDa proteins that are involved in the resolution of either cointegrate intermediates of the replicative transposition process or plasmid multimers. They are site-specific recombinases that act via a serine residue located close to their N-termini, forming a phosphoserine intermediate and promoting DNA strand exchange at directly repeated target sites. Resolvases and closely related invertase enzymes cleave their targets in a directional manner, forming a 2-bp staggered cut at the core of the target site (Smith and Thorpe, 2002). The residues at the ends of Tn*4451* resemble the target sites of several invertases, and these residues are critical for the excision process (Crellin and Rood, 1997). TnpX-mediated excision of Tn*4451* from its target site results in the formation of a nonreplicating circular DNA molecule (Bannam et al., 1995) that is the circular intermediate of the transposition process (Lyras and Rood, 2000b). Formation of this intermediate brings together a 35 box located at the right end of the element and a 10 box at the left end of the element, forming a perfectly spaced *tnpX* promoter that we have postulated is required to ensure that the circular element is subsequently inserted onto a target site located on another replicon, such as a plasmid or the chromosome (Lyras and Rood, 2000b). In its inserted state this promoter is disrupted, and expression of the *tnpX* gene, and, therefore, excision, is dependent upon promoter sequences found outside the element, providing a mechanism for reducing the level of excision and preserving its more stable integrated state.

The N-terminal resolvase domain of TnpX is essential for its function; mutation of residues conserved in resolvase proteins, including the catalytic Ser-15 residue, eliminates the ability of TnpX to catalyze either the excision (Crellin and Rood, 1997) or insertion reactions (Lyras and Rood, 2000b). These reactions are distinct. Although the insertional target sites of Tn*4451* resemble the joint of the circular intermediate (Crellin and Rood, 1997), even containing central GA residues, TnpX binds much less efficiently to these target sites compared to the circular intermediate joint or the left or right ends of the element (Adams et al., 2004). These results imply that despite the fact that both excision and insertion involve the same resolvase-mediated catalytic activity, they are distinct processes, with different synaptic complexes being involved.

TnpX is the only transposon-encoded protein required for transposition of Tn*4451* (Lyras et al., 2004). Evidence for this conclusion came from in vivo studies that systematically involved the construction of deletions in each of the other Tn*4451* genes and from in vitro studies, which demonstrated that purified TnpX could catalyze excision in the absence of any other protein. Further studies have shown that TnpX binds to a region that encompasses the ends of the element and have led to the identification of the DNA binding region, between amino acids (aa) 492 and 597 (Adams et al., 2004). Detailed analysis of the TnpX protein and its derivatives has shown that it has at least two major DNA binding domains, the oppositely charged aa 533–583 region, which is essential for biological activity, and the cysteine-rich aa 597–707 C-terminal domain, which is not essential (Lucet et al., 2005).

Gene Manipulation in *C. perfringens*

There are two generally accepted protocols for the electroporation-mediated transformation of *C. perfringens* cells; one of which involves late logarithmic phase cells (Allen and Blaschek, 1990), the other involving lysostaphin-treatment of early logarithmic phase cells (Scott and Rood, 1989). Highest transformation frequencies are obtained with derivatives of strain 13, which lacks a restriction system. An alternative, especially for studies requiring an enterotoxin producing strain, involves the use of SM101 (a transformation-proficient derivative of NCTC 8798; Zhao and Melville, 1998). As already described, specific shuttle plasmids can also be introduced into *C. perfringens* by conjugation from *E. coli* (Lyras and Rood, 1998a).

Electroporation-mediated transformation of *C. perfringens* cells by suicide vectors has been used to generate chromosomal or plasmid mutants by homologous recombination. Double crossovers in genes such as the α-toxin structural gene *plc*, the perfringolysin O structural gene *pfoA*, and Tn*4451*-encoded *tnpZ* gene located on pIP401 have been constructed and used to analyze gene function (Awad et al., 1995; Bannam et al., 1995). Other studies have involved the construction of *colA* (Awad et al., 2000), *cpe* (Sarker et al., 1999) and *virR* (Shimizu et al.,

1994) mutants. Transposon mutagenesis with Tn*916* has also been used to isolate mutants in *C. perfringens*, but this method is complicated by the frequent occurrence of multiple insertions (Awad and Rood, 1997).

Genomics

C. perfringens is the only histotoxic clostridium to have been completely sequenced (Shimizu et al., 2002). The transformable virulent strain 13 comprises 3,031,430 bp, with a G+C content of 28.6 mol%, and potentially encodes 2660 proteins (Fig. 3). In addition, the sequence of the type strain ATCC13124 is complete but not yet published and that of the enterotoxin producer SM101 is nearing completion; both sequences are available from {The Institute for Genome Research website}. The strain 13 genome is a little smaller than that of most other *C. perfringens* isolates (Canard et al., 1992).
Fig. 3. Complete genetic map of the strain 13 chromosome. Ring 1 shows the coding sequence of each strand; ring 2 shows the positions of the 10 rRNA operons; ring 3 shows the variation in the mol% (G+C) content; ring 4 shows the position of the genes involved in sporulation and germination; and ring 5 shows the position of virulence-related genes. Legend to genes in ring 1: intermediary metabolism and fermentation (yellow), information pathways (pink), regulatory proteins (sky blue), conserved hypothetical proteins (orange), proteins of unknown function (light blue), insertion sequences and phage-related functions (blue), stable RNA molecules (purple), cell wall and cell processes (dark green), virulence genes (red), detoxification and adaptation (white), and sporulation and germination (black). From Shimizu et al. (2002), with permission.

Analysis of the strain 13 genome yielded considerable insight into the metabolism and pathogenic potential of *C. perfringens* (Shimizu et al., 2002). Consistent with the fact that *C. perfringens* ferments many different sugars and obtains all of its energy from substrate level phosphorylation, there were many homologues of genes encoding glycolytic enzymes but no homologues of genes encoding enzymes involved in the tricarboxylic acid cycle or proteins involved in the respiratory chain. The fact that *C. perfringens* must be provided with many different exogenous amino acids if it is to grow in minimal medium (Sebald and Costilow, 1975) was explained by the absence of genes required for the biosynthesis of most of these amino acids. Comparison with the *Bacillus subtilis* genome revealed the presence of 61 genes related to either sporulation or germination, although approximately 80 such genes were absent, especially those involved in spore coat biosynthesis and some germination genes. Many of the genes involved in the regulatory Spo0A phosphorelay were also missing. Clearly, much work remains to be done before the sporulation process in *C. perfringens* is understood; however, note that strain 13 does not sporulate as well as many other *C. perfringens* isolates.

At least 24 putative virulence genes were identified (Shimizu et al., 2002), but of these genes, only *plc* and *pfoA* have been shown to be involved in virulence (Awad et al., 1995; Awad et al., 2001). The designation of the remaining genes as virulence genes (Shimizu et al., 2002) must be regarded as highly speculative. For example, in addition to the *pfoA* gene, four genes were identified by comparative sequence analysis and proposed to encode hemolysins. However, two separate studies have shown that a *pfoA* mutant is nonhemolytic (Awad et al., 1995; Awad and Rood, 1997). Similarly, five separate hyaluronidase genes were identified and postulated to be involved in virulence (Shimizu et al., 2002) though only *nagH* has been shown to actually encode a functional hyaluronidase (Canard et al., 1994) and there is no evidence that hyaluronidase is involved in the pathogenesis of *C. perfringens* infections. Finally, numerous genes that encode the sensor histidine kinases and response regulators that comprise two-component signal transduction systems were identified (Shimizu et al., 2002). These genes include those encoding the well known VirS/R system (Rood, 1998).

A surprising finding of the strain 13 genome project was the discovery that this strain carries a previously unknown 54,310-bp plasmid, pCP13 (Shimizu et al., 2002). This plasmid carries many plasmid-related genes, a nonfunctional homologue of the *cbp2* β2-toxin gene (D. Fisher and

B. McClane, personal communication) but no homologues of known conjugation genes. Whether pCP13 is conjugative or confers any virulence properties on its host strain is not known.

Epidemiology

The critical epidemiological factor in histotoxic clostridial diseases is the production of endospores. These spores are resistant to environmental stress and can survive for long periods in the soil, retaining the ability to germinate and produce extracellular toxins when they are introduced into the nutrient rich environment of the human or animal body.

Spores are introduced into the body by contamination of gunshot or other wounds with soil and intestinal or fecal material. Gas gangrene is, therefore, the classical disease of human conflict or war. In the First World War and, prior to the introduction of penicillin, in the Second World War, gas gangrene was a major consequence of the contamination of gunshot wounds and a very significant cause of death (MacLennan, 1962). More modern causes of predisposing tissue damage include other traumatic injuries, such as those resulting from car accidents and intestinal surgery. Irrespective of the cause of the injury, the anaerobic environment created by the traumatic tissue damage provides the stimulus required to enable spore germination, vegetative growth, and the subsequent production of extracellular toxins. Notably, *C. perfringens* requires predisposing conditions to cause disease and is essentially a saprophytic soil organism. The primary purpose of the extracellular toxins and enzymes appears to be hydrolysis of organic material in the soil, presumably to provide nutrients for bacterial growth. The optimal temperature for the production of *C. perfringens* α-toxin, therefore, is 20°C not 37°C (Matsushita et al., 1996).

Clostridium perfringens-mediated Gas Gangrene

Gas gangrene can be defined as a histotoxic infection of muscle tissue that involves extensive toxemia, local edema, tissue necrosis, and gas production (MacLennan, 1962). The most common cause of gas gangrene is *C. perfringens*, although other clostridial species including *C. septicum*, *C. novyi*, *C. sordellii*, *C. histolyticum* and *C. fallax*, may be involved (MacLennan, 1962).

Infection of a superficial wound with a few vegetative cells or spores of *C. perfringens*, or another histotoxic clostridium, does not normally lead to histotoxic disease (MacLennan, 1962). In such circumstances the host tissues are highly oxygenated, which is not a suitable environment for the growth of these anaerobic bacteria. In addition, the ready supply of phagocytic cells provided by the normal inflammatory response helps to remove the infecting bacteria. However, when the wound is so traumatic that the blood supply to the tissues is affected, then the resultant ischemia provides ideal spore germination and growth conditions and limits the access of phagocytic cells to the invading anaerobes. If the inoculum is sufficiently large, as in a wound that results from intestinal perforation, then the bacteria may themselves help to create the appropriate anaerobic environment. However, the key factor in the development of disease is generally major disruption of the blood supply to the tissues (MacLennan, 1962).

Once *C. perfringens* cells are established and growing in the tissues they produce copious amounts of H_2 and CO_2 as a result of their fermentative metabolism, thereby helping to maintain an anaerobic environment. It is this bacterial gas production that gives the disease its common name of gas gangrene. In addition, at least two of the extracellular toxins produced by *C. perfringens*, α-toxin and perfringolysin O, act to prevent the influx of leukocytes from any blood vessels that remain intact, thereby protecting the developing focus of bacterial infection from the innate immune system. The absence of a significant inflammatory response is a hallmark of *C. perfringens*-mediated gas gangrene and has been recognized for many years (McNee and Dunn, 1917; MacLennan, 1962).

Extensive growth of the bacteria, followed by extracellular toxin production, leads to massive tissue necrosis. The onset of very severe and intense pain at the focus of infection is a very common feature and is a clear indication of major vascular collapse (MacLennan, 1962). Another key feature of this disease is tissues that are rapidly undergoing necrosis do not bleed (McNee and Dunn, 1917; MacLennan, 1962). Although the actual mechanisms by which these effects are mediated are not known, it has been postulated that they result from thrombosis of the microvasculature and resultant effects on the arterial blood supply (Bryant, 2003a). Disease progression is very rapid once a focus of infection is established, with previously healthy oxygenated tissue being quickly taken over by the advancing front of necrosis (McNee and Dunn, 1917; Bryant, 2003a). Death can occur within 24-48 h if the patient does not receive appropriate treatment. Death results from systemic toxemia, shock, and multiorgan failure, with extracellular toxins, primarily α-toxin, having effects on

systemic blood pressure and cardiac function and leading to hemodynamic collapse (Stevens, 2000; Stevens and Bryant, 2002).

Treatment involves a combination of massive doses of antibiotics, usually penicillin since *C. perfringens* is always susceptible to this antibiotic, coupled with surgical debridement of the wound. Amputation is often the only surgical option, as even treatment by antibiotics to which the bacterium is susceptible may fail to stop the progression of the disease, presumably because they do not get into the lesion. Rapid treatment and the location of the focus of infection are the key factors in patient survival (Stevens and Bryant, 2002).

Pathogenesis: Role of α-Toxin and Perfringolysin O

The demonstration in 1941 that *C. perfringens* α-toxin had lecithinase activity was the first time that a bacterial toxin had been shown to be an enzyme (MacFarlane and Knight, 1941). This toxin is the only toxin shown to be essential for *C. perfringens*-mediated gas gangrene (Awad et al., 1995). Although other toxins such as perfringolysin O and collagenase are not essential (Awad et al., 1995; Awad et al., 2000), these toxins, together with other extracellular toxins and enzymes such as hyaluronidase and sialidases, still may play an important role in the disease process.

Evidence for the essential role of α-toxin in disease comes from two independent studies. The construction and analysis of recombinant variants of α-toxin revealed that although the N-terminal domain (aa 1–249) could invoke an excellent antibody response in mice, these antibodies were not immunoprotective. By contrast, immunization with the C-terminal α-toxin domain (aa 247–370) could protect against experimental infection, providing evidence that

α-toxin is a critical toxin (Williamson and Titball, 1993). Recombinant vaccinia viruses producing the C-terminal domain could also be used to protect mice against a lethal challenge (Bennett et al., 1999). More recent studies have shown that immunization with the C-terminal α-toxin domain localizes the infection, reduces thrombosis and leukostasis, and prevents more systemic effects such as ischemia of the peripheral tissues (Stevens et al., 2004).

Definitive proof of the essential role of α-toxin came from genetic studies that involved the construction of an α-toxin null mutant by allelic exchange (Awad et al., 1995). The resultant mutant was avirulent in a mouse myonecrosis model, with virulence being restored when the mutant was complemented with a wildtype α-toxin gene. These studies and subsequent experiments also showed that α-toxin was the major toxin involved in the prevention of leukocyte influx into the infected lesion (Awad et al., 1995; Stevens et al., 1997; Ellemor et al., 1999; Fig. 4).

The precise mechanism by which leukocyte influx is inhibited is uncertain, but it appears to involve the α-toxin-mediated formation of intravascular aggregates of platelets and leukocytes (Bryant et al., 2000a). Injection of purified recombinant α-toxin into the muscle of rats leads to a rapid and specific occlusion of blood flow due to the formation of aggregates, initially in the venules but then in the arteries (Bryant et al., 2000a; Bryant et al., 2000b). Examination of these aggregates reveals that they stain strongly for the surface bound platelet adherence antigen P-selectin, suggesting that platelet aggregation is a major factor in their formation (Bryant et al., 2000a). This process involves the activation of a fibrinogen receptor, gpIIbIIIa or CD41, since monoclonal antibodies against gpIIbIIIa, or peptides that mimic fibrinogen, significantly reduce αtoxin-mediated platelet binding to granulocytes (Bryant et al., 2000b). By contrast, antibodies active against P-selectin have no effect on
Fig. 4. Effect of *C. perfringens* α-toxin on muscle histopathology. Hematoxylin and eosin stained muscle sections obtained from mice infected with A (wild-type *C. perfringens*) and B) an isogenic plc mutant. The wild-type results in the extensive muscle necrosis and the presence of leukocyte aggregates and thrombosis in the blood vessels (arrows). None of these features is observed with the mutant; note the extensive leukocyte infiltration. From Ellemor et al. (1999), with permission.

α-toxin-induced aggregation. It has been suggested that agents that target gpIIbIIIa or its activation process might prove to be effective in the treatment of gas gangrene (Bryant et al., 2000b; Bryant et al., 2003b).

Further studies have shown that activation by α-toxin results in the depletion of internal calcium stores and calcium influx, which leads to activation of surface gpIIbIIIa, presumably by some sort of conformational change, and mobilization of stored gpIIbIIIa to the cell surface (Bryant et al., 2003b). Still unknown is how treatment of cells with α-toxin leads to these calcium-dependent changes, but the process does not appear to involve effects of the phospholipase C reaction product, diacylglycerol, on the protein kinase C cascade.

The α-toxin-mediated production of hydrolytic products such as diacylglycerol and ceramide has been implicated in the induction of proinflammatory changes in endothelial cells (Bunting et al., 1997). Treatment of human endothelial cell monolayers with purified α-toxin leads to the protein kinase C- and dose-dependent synthesis and release from the cells of the proinflammatory platelet activating factor (PAF) and the arachidonic acid derivative, prostacyclin, a strong vasodilator. These α-toxin treated cells have an increased capacity to bind to neutrophils, suggesting that the action of this toxin on endothelial cells may also play a role in leukocyte adhesion in the local vascular system and in vascular homeostasis. This process may be mediated by the upregulation of P-selectin expression in endothelial cells (Bunting et al., 1997). α-Toxin treatment also leads to the adhesion of rabbit neutrophils to fibrinogen and fibronectin (Ochi et al., 2002). Other studies have shown that α-toxin stimulates the upregulation of endothelial leukocyte adhesion molecule-1 (ELAM-1), intercellular adhesion molecule-1 (ICAM-1), and interleukin (IL)-8 expression, whereas perfringolysin O stimulates early ICAM-1 expression (Bryant and Stevens, 1996). For a comprehensive review of the effects of both α-toxin and perfringolysin O on thrombosis and leukostasis, see the excellent review by Bryant (2003a).

Genetic studies have also been carried out on the structural gene for the θ-toxin or perfringolysin O, *pfoA*, and the *colA* gene, which encodes κ-toxin or collagenase. Mutants that were unable to produce either perfringolysin O or collagenase still caused clostridial myonecrosis in mice, indicating that these toxins were not essential for virulence (Awad et al., 1995; Awad et al., 2000). However, perfringolysin O is still important in the disease process. Perfringolysin O upregulates the CD11b/CD18 adhesin on the surface of neutrophils (Bryant et al., 1993). Delayed spread of muscle necrosis was observed with the *pfoA* mutant as well as increased leukocyte infiltration, although not to the extent of the *plc* mutant (Ellemor et al., 1999). Finally, evidence that α-toxin and perfringolysin O have synergistic effects was obtained from virulence studies carried out by complementation of a *plc pfoA* double mutant (Awad et al., 2001). In these experiments complementation with the wild-type *plc* and *pfoA* genes produced a pathology that was more severe than that observed with just the *plc* gene.

Most strains of *C. perfringens* produce one or more sialidases, generally the smaller intracellular NanH enzyme (43 kDa) and the larger extracellular NanI enzyme (73 kDa) (Roggentin and Schauer, 1997; Takamizawa et al., 2004). The sequenced isolate of *C. perfringens*, strain 13, does not have *nanH* but has *nanI* and another potential extracellular sialidase gene, *nanJ* (Shimizu et al., 2002). Little is known about the role of any of these sialidases in disease, and no sialidase mutants have been constructed and virulence-tested. However, recent studies have shown that sialidase treatment may increase the sensitivity of cell cultures to α-toxin, suggesting that α-toxin and sialidase may also act synergistically (Flores-Díaz et al., 2004). It was proposed that surface gangliosides, which contain terminal sialic acid residues, protect the cell surface from the effects of α-toxin. These results are consistent with earlier studies that showed that Chinese hamster cell lines that had a mutation in UDP-glucose pyrophosphorylase and therefore were unable to produce UDP-glucose, a cell surface glycoconjugate precursor, were hypersensitive to the cytotoxic effects of α-toxin (Flores-Díaz et al., 1998).

Other workers have focused on the early stages of infection and have analyzed the action of α-toxin and perfringolysin O on macrophages (O'Brien and Melville, 2000; O'Brien and Melville, 2003; O'Brien and Melville, 2004). *Clostridium perfringens* cells have been shown to survive in a particular murine macrophage cell line, J774-33, where they escape from the phagolysosome and enter the cytoplasm (O'Brien and Melville, 2000). Phagocytosis of *C. perfringens* cells appears to involve receptors that may interact with mannose or glucuronic acid residues present in the *C. perfringens* capsule (O'Brien and Melville, 2003). Subsequent studies carried out on mouse peritoneal macrophages with *pfoA* and *plc* mutants suggest that both α-toxin and perfringolysin O are important for the survival of *C. perfringens* inside these cells, with perfringolysin O, and to a lesser extent α-toxin, also being important in escape from these macrophages (O'Brien and Melville, 2004). However, these data, and the subsequent mouse

virulence studies, need to be confirmed by complementation with the wildtype toxin genes. It was suggested that escape from the macrophage was important in the early stages of infection when cell numbers were lower. Evidence to support this hypothesis was obtained from *in vivo* studies carried out in mice using a relatively low infective dose. Under these conditions, both the *pfoA* and *plc* mutants had a lower survival rate in the muscle tissue(O'Brien and Melville, 2004).

Toxin Structure-Function Relationships

α-Toxin

The mature *C. perfringens* α-toxin is a 370-aa zinc metallophospholipase C. Zinc ions are required for enzymic activity, and calcium ions are essential for binding to the lipid membrane (Moreau et al., 1988). The toxin has phospholipase C activity, hydrolyzing phosphatidylcholine to diacylglycerol and phosphorylcholine and also has sphingomyelinase activity, hydrolyzing sphingomyelin to produce ceramide (Titball and Rood, 2000; Ochi et al., 2004). Both catalytic activities are the reflection of the same active site, which is located in the N-terminal domain of the toxin. The end products are important cell signaling molecules. Diacylglycerol is capable of activating the arachidonic acid pathway and the protein kinase C regulatory cascade (Titball and Rood, 2000), and ceramide causes apoptosis (Ohanian and Ohanian, 2001). The hemolytic activity of α-toxin is related to the presence of a distinct C-terminal domain and sphingomyelinase activity, which leads to α-toxin-induced activation of the sphingomyelin metabolic cascade (Ochi et al., 2004).

Determination of the crystal structure of α-toxin has revealed considerable information about its mode of action. The toxin consists of two major domains (Fig. 5), an N-terminal domain (aa 1–246) that is α-helical and contains the phospholipase C active site and a C-terminal domain (aa 256–370) that primarily consists of β-sheets (Naylor et al., 1998). These domains are joined by a short flexible linker (aa 247–255). The N-terminal domain consists of nine α-helices that are folded in a very similar manner to the nontoxic *Bacillus cereus* phosphatidylcholine-preferring phospholipase C (PC-PLC), which does not have the C-terminal domain. This domain contains an active site that binds three zinc ions.

The immunoprotective C-terminal domain is essential for toxicity and hemolytic activity, consists of two four-stranded β-sheets, and contains a key calcium-binding site (Fig. 5). This domain
Fig. 5. Crystal structure of *C. perfringens* α-toxin. The crystal structure is represented as a ribbon diagram, with a color transition from the N-terminus (blue) to the C-terminus (red). As shown, the active site is in the α-helical N-terminal domain and the calcium-binding site is in the β-sheet C-terminal domain. From Fig. 2 of Titball and Rood (2000), with permission.

is a structural homologue of eukaryotic C2-lipid binding domains such as the C-terminal domain of human pancreatic lipase and the N-terminal domain of soybean lipoxygenase-1, which have an eight-stranded β-sandwich structure (Guillouard et al., 1997; Naylor et al., 1998). C2-domains are present in many eukaryotic signaling proteins and are involved in lipid-second messenger signal transduction pathways. The α-toxin C2 domain is required for the binding of the toxin to lipids at the host cell membrane surface and may mimic host cell proteins with similar C2 domains.

Further evidence that the C-terminal domain conferred hemolytic activity and cellular toxicity was obtained from domain swapping experiments between the *C. perfringens* α-toxin and the phospholipase C from *Clostridium bifermentans* (Jepson et al., 1999). The latter enzyme has a similarly sized C-terminal domain and equivalent phospholipase C activity on egg yolk emulsion but is 100 times less toxic. A hybrid protein comprised of the N-terminal domain of the *C. bifermentans* enzyme and the C-terminal domain of the *C. perfringens* enzyme ($N_{bi}C_{\alpha}$) was shown to be significantly more hemolytic and toxic for mice than the former enzyme. When similar domain swapping experiments were carried out between *C. perfringens* α-toxin and phospholipase C from *Bacillus cereus*, which does not have a C-terminal domain, the resultant $N_{bc}C_{\alpha}$ fusion protein was also hemolytic, although at only 0.1% of the wildtype α-toxin level (Nagahama et al., 2002). Furthermore, when separate nonhemolytic polypeptides consisting of the

N-terminal ($C_{\alpha1-250}$) and C-terminal ($C_{\alpha251-370}$) α-toxin domains were incubated together, hemolytic activity was restored. Similar complementation results were obtained by other workers using α-toxin mutants (Guillouard et al., 1997). These results are consistent with the observation that the C-terminal domain is required for α-toxin to bind to erythrocyte membranes.

Further comparative analysis of the wild-type *C. perfringens* and *C. bifermentans* enzymes revealed that in the C-terminal domain of the α-toxin there were three aa that appeared to be involved in membrane recognition but were different in the *C. bifermentans* enzyme (Jepson et al., 2001). Conversion of the α-toxin to a derivative that had the *C. bifermentans*-derived sequences (D269Y, Y331L and F334I) demonstrated that Tyr-331 and Phe-334 were both essential for full cytotoxic activity. The D269Y substitution altered the ability of the protein to bind Ca^{+2}; it had minimal effect on phospholipase C activity but led to increased cytotoxic activity, presumably because of an enhancement of the ability of the toxin to bind to the cell membrane (Jepson et al., 2001). These residues are all located on the putative membrane-binding surface of the α-toxin C-terminal domain.

Clostridium perfringens α-toxin appears to have both active and inactive conformations, with calcium binding being required for activation. There are three low affinity Ca^{+2} binding sites in the C-terminal domain, Ca1, Ca2 and Ca3 (Naylor et al., 1999). Asp-269 and Asp-336 have been shown to be required for the Ca^{+2} activation process (Guillouard et al., 1997) and are involved in Ca^{+2} binding at Ca1, along with Gly-271 and Ala-337 (Naylor et al., 1998). The Ca2 site involves Asp-293, Asn-294, Gly-296 and Asp-298, whereas Thr-272, Asp-273, Asn-297 and Asp-298 are implicated at Ca3. Note that amino acids that are adjacent in the linear amino acid sequence are involved in Ca binding but at different sites (Naylor et al., 1999). These authors suggested that if these sites are involved in binding to both Ca^{+2} and the host membrane, then the active site will be able to bind to its phosphatidylcholine substrate without disrupting the phospholipid membrane. Other experiments have shown that mutation of Asp-269, Asp-336, Tyr-275 and Tyr-307, and other residues in the C-terminal domain, significantly affects sphingomyelinase activity and toxicity (Alape-Girón et al., 2000).

In addition, there are two important surface-exposed hydrophobic residues, Trp-214, in the N-terminal domain, and Phe-334, in the C-terminal domain. When the toxin-membrane interface is modeled (Naylor et al., 1998), these residues appear to be inserted into the phospholipid bilayer, implying that they are involved in interactions with the cell membrane. PC-PLC, which is not hemolytic or toxic, does not have either the C2 domain or Trp-214.

Random mutagenesis has also been used to identify residues in the C-terminal domain that are required for biological activity. The three α-toxin mutants (D293S, K330E and D305G) analyzed had reduced hemolytic and cytotoxic activity (Walker et al., 2000). The D293S enzyme was Ca^{+2}-activated, which is consistent with this mutated protein having a reduced ability to bind Ca^{+2} and is in agreement with previous conclusions that Asp-293 was involved in Ca^{+2} binding at Ca2 (Naylor et al., 1999).

α-Toxin exists in two conformational forms, known as the open and closed conformations (Naylor et al., 1999). The original crystal structure was from an enzyme with the active site open (Naylor et al., 1998). Subsequently, the structure of an enzyme in the closed inactive conformation was determined (Eaton et al., 2002). Analysis of this structure provided evidence that movement of two loops in the N-terminal domain is critical for the opening and closing of the active site of the enzyme. It was postulated (Eaton et al., 2002) that the previously characterized T74I (Nagahama and Sakurai, 1996) and F69C (Guillouard et al., 1996) α-toxin mutants had reduced activity because these amino acid substitutions altered the conformation of loop 1 in the N-terminal domain.

The *C. absonum* α-toxin has similar phospholipase C activity to the *C. perfringens* α-toxin and is 1.5 times more hemolytic but only has half the toxicity (Clark et al., 2003). Comparative analysis of the crystal structures revealed a similar overall structure to the open form of *C. perfringens* α-toxin. A major difference was observed in the conformation of the aa 72–93 loop, which is more prominent in the *C. absonum* toxin; this change suggested a role for W84 in membrane binding. Conserved residues previously shown (Nagahama et al., 1995; Nagahama et al., 1997; Nagahama et al., 2000; Guillouard et al., 1996; Guillouard et al., 1997) to be involved in Zn coordination in the *C. perfringens* α-toxin (Trp-1, His-11, His-68, His-126, His-136, His-148 and Glu-152) and to be essential for enzymic activity are conserved in the *C. absonum* toxin (Clark et al., 2003). Note that the results of extensive site-directed mutagenesis studies on the *C. perfringens* α-toxin are summarized in two major reviews (Titball and Rood, 2000; Titball and Rood, 2002).

A divergent *C. perfringens* α-toxin has been characterized from a strain (SWCP) of *C. perfringens* isolated from a swan that died from a gastrointestinal *C. perfringens* infection (Justin et al., 2002). This variant toxin had 57–58 aa sequence changes compared to other *C. perfringens* α-toxins, with the altered aa distributed

relatively evenly throughout the protein. The active site was conserved. By comparison, other α-toxins from avian strains of *C. perfringens* had only one to six sequence changes (Sheedy et al., 2004). The SWCP α-toxin had an altered substrate specificity but was still hemolytic. Examination of its crystal structure revealed that it was similar to that of the open form of the previously determined α-toxin structure (Justin et al., 2002). It had the usual three zinc ions at the active site as well as the β-sandwich C-terminal domain. However, there were sequence and structural changes in one of the three Ca^{+2} binding pockets and its associated loop.

Perfringolysin O

Perfringolysin O is member of the cholesterol-dependent cytolysin (CDC) family of pore-forming cytotoxins, which was previously known as the "thiol-activated cytolysin family." The family includes perfringolysin O, streptolysin O, listeriolysin and pneumolysin (Billington et al., 2000). These toxins are closely related 40–60 kDa polypeptides that bind to cholesterol residues on the target cell membrane. Perfringolysin O has been shown to bind specifically to lipid rafts, which are cholesterol-rich domains in mammalian cells (Waheed et al., 2001; Ohsaki et al., 2004). Like other members of this family, perfringolysin O has an essential tryptophan-rich undecapeptide sequence, ECTGLAWEWWR, located in its C-terminal region (aa 430–440). Replacement of these tryptophan residues with phenylalanine, but not replacement of tryptophan residues located outside the undecapeptide, significantly reduced the ability of the resultant toxin to bind to and lyse red blood cells (Sekino-Suzuki et al., 1996), although subsequent studies have shown that these tryptophan residues are not required for cholesterol binding (Shimada et al., 1999). Modification of Cys-431 with a bulky thiol-blocking reagent also reduces the ability of the toxin to bind to membranes (Iwamoto et al., 1990). However, studies on other CDCs showed that cysteine to alanine replacements had little effect on biological activity (Michel et al., 1990). Therefore, the conserved thiol group of CDCs is not required for biological activity, which is why they are no longer known as thiol-activated cytolysins. Analysis of the structure of perfringolysin O explains these results as it predicts that bulky chemical modification of Cys-459 would lead to conformational changes in the Trp-rich loop and prevent cholesterol binding (Rossjohn et al., 1997). Chemical modification of the histidine residues in perfringolysin O also reduces activity and oligomerization in the cell membrane (Nakamura et al., 1999). Further studies have shown that the last

21 aa of perfringolysin O (aa 452–472) are required to maintain the native conformation of perfringolysin O, and deletion of the last three aa significantly reduces cholesterol binding and hemolysis (Shimada et al., 1999).

Production of perfringolysin O occurs in early logarithmic growth phase and is dependent upon the VirS/VirR two-component signal transduction system (Rood, 1998). The toxin is synthesized with a leader peptide sequence, which is cleaved upon passage through the cell membrane. The mature 52.7-kDa (472 aa) toxin has the ability to lyse red blood cells from many species and is the reason for the clear zone of hemolysis observed around *C. perfringens* colonies on blood agar. At the target cell surface the toxin forms aggregates that penetrate the phospholipid bilayer, form an oligomeric pore, and eventually lead to cell lysis.

The crystal structure of the toxin has been determined (Rossjohn et al., 1997) and the protein shown to have four distinct domains (Fig. 6), with the undecapeptide being located at the tip of domain 4. The toxin has a highly elongated structure that is rich in β-sheets (40%). The peripheral location of the undecapeptide prompted the suggestion that the tip of this domain was responsible for membrane insertion and oligomerization to form the pore that traversed the membrane (Rossjohn et al., 1997). Subsequently, fluorescence spectroscopy and cysteine scanning mutagenesis studies were used to identify regions of perfringolysin O that are no longer sensitive to water when the toxin binds to the cell membrane (Shepard et al., 1998; Shatursky et al., 1999). These regions are located in domain 3 of the toxin, which consists of a mixture of α-helices and β-sheets. Similar analysis has shown that domain 4 does not span the target membrane, only the hydrophobic tips of this domain make contact with the phospholipid bilayer of the target cell (Ramachandran et al., 2002; Czajkowsky et al., 2004). Furthermore, domain 4 does not make significant contact with adjacent monomers in the membrane-inserted oligomer (Ramachandran et al., 2002). This domain is still critical for cholesterol binding, although the precise nature of that interaction remains to be determined.

The current model for the insertion of perfringolysin O into the cell membrane involves the transition of α-helices in domain 3 of the soluble monomer to form two extended amphipathic antiparallel β-sheets in the membrane-inserted oligomeric complex (Fig. 6). The end-result is a membrane-spanning dual β-hairpin structure (Shatursky et al., 1999). The major theoretical problem with this model is that even after binding of the tips of domain 4 to the membrane, the amphipathic β-hairpins in domain 3 are too far
Fig. 6. Crystal structure of perfringolysin O and conformational transitions in the insertion of perfringolysin O into the cell membrane. A) A ribbon representation of perfringolysin O is shown, with the domains indicated. The conserved undecapeptide is located at the extended tip of domain 4. B) Conformational change of transmembrane helices 2 and 3 in domain 3 leads to the formation of a dual extended β-hairpin structure. From Fig. 4 of Shatursky et al. (1999), with permission.

Fig. 7. Schematic model of the prepore to pore transition of perfringolysin O. It is proposed that the vertical collapse of domain 2 brings the transmembrane domains of domain 3 close enough to the cell surface to enable membrane penetration by the amphipathic β-helices. Note that of the six residues tested, Q433 is the only residue quenched by the formation of the prepore complex. From Fig. 8 of Czajkowsky et al. (2004), with permission.

from the surface of the membrane to undergo membrane insertion. However, recent studies (Czajkowsky et al., 2004) involving time-lapse atomic force microscopy have shown that upon binding to the membrane, conformational changes in domain 4 lead to a novel vertical collapse of the elongated perfringolysin O structure (from 113 Å to 73 Å), bringing the domain 3 β-hairpins close enough to traverse the membrane (Fig. 7). Collisional quenching studies provide further evidence for this conclusion by demonstrating that after it makes contact with the cell membrane, the toxin monomer remains upright and does not bring domain 3 closer to the surface by a tilting-like mechanism. It is postulated that contraction of the extended structure of domain 2 is responsible for the vertical contraction that leads to membrane insertion (Czajkowsky et al., 2004).

Finally, a prepore complex appears to be formed prior to the insertion of the β-hairpins into the membrane (Shepard et al., 2000). Recent studies suggest that perfringolysin O is primarily a dimer in solution (Solovyova et al., 2004). The final pore is proposed to result from hydrogen-bonding between adjacent β-hairpins in the oligomeric membrane-bound complex, forming a β-barrel structure that contains about 50 monomers (Shepard et al., 1998; Shatursky et al., 1999). The oligomerization process appears to result from the formation of a monomer-monomer interface formed by a previously buried β-strand (from domain 3) in each monomer (Ramachandran et al., 2004). The formation of this interface involves a φ-stacking interaction between the aromatic rings of Tyr-181 and Phe-318, of the β1 and β4 strands, respectively, of domain 3. The trigger for the conformational changes involved in this process is contact of domain 4 with the cell membrane.

CHAPTER 1.2.24

The Genera *Desulfitobacterium* and *Desulfosporosinus*: Taxonomy

STEFAN SPRING AND FRANK ROSENZWEIG

Introduction

Members of the genera *Desulfitobacterium* and *Desulfosporosinus* represent a clade of strictly anaerobic, rod-shaped, and sporeforming bacteria within the phylum Firmicutes, previously also known as the "low G+C Gram-positive bacteria."

The taxonomic and environmental significance of microorganisms belonging to this group escaped the attention of microbiologists for a long time and was only recently revealed, although the first representative species was already isolated in 1959. This species, however, was wrongly described as *Desulfovibrio orientis* (Adams and Postgate, 1959). Later the taxonomic affiliation of this bacterium to the Gram-positive sulfate reducers was recognized and it was reclassified as *Desulfotomaculum orientis* (Campbell and Postgate, 1965). Under this name it was included in the Approved Lists of Bacterial Names (Skerman et al., 1980). In the course of a phylogenetic analysis of the genus *Desulfotomaculum*, the separate taxonomic position of this species was revealed and the novel genus *Desulfosporosinus* was proposed with *Dsp. orientis* as type species (Stackebrandt et al., 1997). Some years earlier, Utkin et al. (1994) had already established the genus *Desulfitobacterium* with the type species *Dba. dehalogenans*. The special feature of this species was the reductive dechlorination of halogenated hydrocarbons. At that time this metabolic capability was only known in very few strict anaerobic bacteria. Since then, substantial progress was made in the isolation and description of novel strains representing the genus *Desulfitobacterium*, mainly caused by the growing interest in microorganisms being able to degrade and detoxify halogenated environmental pollutants under anoxic conditions. Currently, five different names of *Desulfitobacterium* species are validly published.

Besides halogenated compounds, several members of this group can also utilize heavy metals, in particular arsenic, as electron acceptor. Within this clade, strain Orex-4 was the first representative for which arsenate reduction was demonstrated. It was originally described as *Desulfotomaculum auripigmentum* (Newman et al., 1997) but has been recently reclassified as *Desulfosporosinus auripigmenti* (Stackebrandt et al., 2003). The capacity to reduce arsenic (As[V]) was later also reported in several strains belonging to the genus *Desulfitobacterium* (Niggemeyer et al., 2001).

Because of their unique metabolic potential, the environmental significance of species belonging to the genera *Desulfitobacterium* and *Desulfosporosinus* is obvious and has been demonstrated in numerous studies (e.g., Robertson et al., 2000; Breitenstein et al., 2001; Lanthier et al., 2001; Nevin et al., 2003). In the future, members of both genera could play a major role in the bioremediation of contaminated sites by the degradation of anthropogenic halogenated compounds or the removal of toxic heavy metals.

Common Traits and Differentiation

According to a recently established taxonomic framework based on the comparative analysis of 16S rRNA gene sequences, the genera *Desulfitobacterium* and *Desulfosporosinus* are affiliated to the family Peptococcaceae within the order Clostridiales (e.g., Boone et al., 2001). The main phenotypic traits characterizing both genera are in good agreement with this phylogenetic placement and include a strict anaerobic metabolism, a Gram-positive cell wall structure characterized by a murein sacculus, motility by means of flagella, and the ability to form endospores. Despite their Gram-positive cell wall architecture many species of this group stain Gram-negative or Gram-variable owing to an unusual thin peptidoglycan layer.

Phylogeny and Related Genera

Members of the genera *Desulfitobacterium* and *Desulfosporosinus* form a coherent phylogenetic group within the Peptococcaceae independent of the algorithm used for tree reconstruction (Fig. 1). The similarity values among 16S rRNA
Fig. 1. Phylogenetic tree based on almost complete 16S rRNA gene sequences showing the positions of members of the genera *Desulfitobacterium* and *Desulfosporosinus* among type species of the family Peptococcaceae. The GenBank/EMBL accession number for each sequence is shown in parenthesis. The tree was reconstructed using the ARB program package (http://www.arb-home.de). It is derived from a distance matrix reconstructed by using the neighbor joining method of Saitou and Nei (1987). Phylogenetic distances were calculated as described by Jukes and Cantor (1969). The sequences of *Bacillus subtilis* (accession no. [{www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide&cmd=search&term=AJ27635}{AJ27635}]) and *Clostridium butyricum* (accession no. [{www.ncbi.nlm.nih. gov/entrez/query.fcgi?db=nucleotide&cmd=search&term= M59085}{M59085}]) were used to define the root (not shown). Only bootstrap values above 80% (1000 resamplings for each node) are shown at the respective branching points. Scale bar represents 10% estimated sequence divergence.

gene sequences within this cluster are 92.9–99.7%. The monophyletic origin of both genera is supported by the phylogenetic comparison of dissimilatory sulfite reductase genes (*dsr*AB). The DsrAB sequences of *Desulfitobacterium hafniense*, *Desulfitobacterium dehalogenans* and *Desulfosporosinus orientis* form a common branch and cluster together with several *Desulfotomaculum* species (Klein et al., 2001). Hence, it can be assumed that representatives of the genus *Desulfitobacterium*, although unable to reduce sulfate, evolved together with *Desulfosporosinus* species from a common sulfate-reducing ancestor. Despite this close phylogenetic relationship, members of both genera do not intermix but form well separated, distinct lineages supported by high bootstrap values. The clear-cut phylogenetic delineation between both genera is also illustrated by a set of signature nucleotides specific for the 16S rRNA genes of each particular genus (Stackebrandt et al., 2003).

The bootstrap values shown in the dendrogram tree clearly illustrate that a stable phylogenetic

relationship exists only with the genera *Dehalobacter* and *Syntrophobotulus*. Type species of other genera within the family Peptococcaceae are only distantly related to *Desulfitobacterium* or *Desulfosporosinus* species. On the other hand, certain members of the genus *Desulfotomaculum* share important phenotypic features with representatives of the genus *Desulfosporosinus*. However, at present the genus Desulfotomaculum is phylogenetically and phenotypically quite heterogenous and probably harbors numerous misclassified species. Hence, the distinction of this genus from other related taxa based on genus-specific traits is difficult and awaits taxonomic rearrangement of the species currently comprising the genus *Desulfotomaculum*.

Phenotypic Characteristics

In Table 1, the related genera *Desulfitobacterium*, *Desulfosporosinus*, *Dehalobacter* and *Syntrophobotulus* are compared, and several important distinguishing traits are listed. Phenotypic characteristics that are common to all representatives of this group include a strict anaerobic metabolism, the Gram-type positive cell wall structure, and a rod-shaped morphology. Ellipsoidal spores causing slight swelling of the cells, motility by means of flagella, and cell wall surface layers are at least present in most tested species. Gram staining depends on the strain or species but in most cases is negative. The G+C content of DNA among species of this group is in the range 45–49 mol%. In all species analyzed so far, LL-diaminopimelic acid (LL-dpm) was identified as the diagnostic diamino acid of the cell wall peptidoglycan. With one exception in all analyzed species LL-diaminopimelic acid (LL-dpm) was identified as the diagnostic diamino acid of the cell wall peptidoglycan. MK-7 represents the major menaquinone of members of the genera *Desulfitobacterium* and *Desulfosporosinus*. Physiological traits common to the genera *Desulfitobacterium* and *Desulfosporosinus* are fermentation of pyruvate, incomplete oxidation of substrates to acetate, and utilization of thiosulfate as terminal electron acceptor.

Representatives of the genus *Desulfosporosinus* can be easily distinguished from the species of other related genera by their ability to grow autotrophically with H_2, fermentation of lactate, and utilization of sulfate as terminal electron acceptor. In contrast, the hallmark feature of members of the genus *Desulfitobacterium* is their ability to use a wide spectrum of chlorinated aliphatic and aromatic compounds for reductive dehalogenation. Still unclear, however, is whether this metabolic potential is really restricted to this genus. Most representatives

Symbols: Nr, not reported; +, positive in most strains; –, negative in most strains; and D, different reaction among strains.

Characteristics given in parenthesis were determined only for a few strains.

Abbreviations: PCE, tetrachlorethylene; Dpm, diaminopimelic acid; and MK-7, -8 and -9, menaquinones with 7, 8 and 9 isoprene units, respectively.

[a]The species epithets *Desulfitobacterium hafniense* and *Dba. frappieri* are subjective synonyms (Niggemyer et al., 2001) and hence are considered as one species in this table.

[b]Data are only available for *Desulfitobacterium* sp. strain PCE1 (Gerrites et al., 1996) and *Dba. dehalogenans* DSM 1916[T] (P. Schumann, DSMZ; personal communication).

[c]Data are only available for the reduction of PCE by *Desulfosporosinus meridiei* and *Dsp. orientis*.

[d]Data are only available for *Desulfitobacterium hafniense* and *Dba. metallireducens*.

[e]Date are only available for the *Desulfitobacterium hafniense* strains DCB-2[T] (Hippe et al., 1997) and TCP-A (Breitenstein et al., 2001).

[f]Data are only available for *Desulfitobacterium* sp. strain PCE1 (Gerrite et al., 1996) and *Desulfitobacterium hafniense* (Christiansen and Ahring, 1996; Gerritse et al., 1999).

[g]Data are only available for *Desulfosporosinus orientis* and *Desulfosporosinus* sp. DSM8344.

Data from The Genus *Desulfotomaculum*, Utkin et al. (1994), Friedrich et al. (1996), Sanford et al. (1996), Newman et al. (1997), Holliger et al. (1998), van de Pas et al. (2001), Niggemyer et al. (2001), Robertson et al. (2001), Finneran et al. (2002), and Stackebrandt et al. (2003).

of other genera, including *Desulfosporosinus* species, were not routinely tested for this characteristic and therefore this ability may have escaped attention. Nevertheless, *Desulfitobacterium* species seem to have a wider spectrum of electron acceptors and *Desulfosporosinus* species seem to have a wider spectrum of utilizable electron donors.

The Genus *Desulfitobacterium*

Habitat

Members of the genus *Desulfitobacterium* were mainly isolated from contaminated environmental sites from around the world. Habitats include soil, freshwater sediment, compost soil, and sewage sludge. Independent of the environmental site, maintenance of anoxic conditions seems to be the most important prerequisite for the proliferation of these bacteria in a specific habitat. Nevertheless, the capacity among *Desulfitobacterium* species to form endospores may promote their survival also under unfavorable growth conditions and thereby contribute to a ubiquitous distribution. Although most known *Desulfitobacterium* strains were isolated from sites contaminated with halogenated pollutants or heavy metals, the distribution of this genus is obviously not restricted to those ecological niches. This was clearly demonstrated by the isolation of *Desulfitobacterium* strains from pristine freshwater sediment (*Dba. dehalogenans*; Utkin et al., 1994) or human feces (strain DP7; Van de Pas et al., 2001). In a cultivation-independent study, soil samples from various sites in Canada were tested for the presence of indigenous *Desulfitobacterium* species by the amplification of DNA with specific polymerase chain reaction (PCR) primers targeting signature regions of their respective 16S rRNA genes. Positive signals were obtained in 31 out of 48 analyzed soil samples. A contamination of the analyzed samples with heavy metals or halogenated compounds had no effect on the presence or absence of *Desulfitobacterium* cells (Lanthier et al., 2001).

Isolation

In studies describing the selective enrichment of *Desulfitobacterium* strains from environmental samples, mainly basal freshwater mineral media were used containing as electron acceptors either halogenated compounds, arsenate (Niggemeyer et al., 2001), or the humic substance analogue anthraquinone-2,6-disulfonate (AQDH; Finneran et al., 2002). Types and concentrations of halogenated compounds used for successful enrichment comprise pentachlorophenol (PCP,

3–5 mg/liter; Bouchard et al., 1996), 2,4,6-trichlorophenol (2,4,6-TCP, 100–200 μM; Breitenstein et al., 2001), 2,3-dichlorophenol (2,3-DCP, 1 mM; Sanford et al., 1996), tetrachloroethene (PCE, 100 μM; Gerritse et al., 1996), and 1,2-dichloroethane (1,2-DCA, 400 μM; De Wildeman et al., 2003). The suitable concentration of the used halogenated compound depends on its toxicity for the dehalogenating population, its solubility in water, and the toxicity of the formed end products. Prior to the isolation of pure cultures in most cases the initial enrichments were further purified by successive transfer in batch cultures or continous incubation in bioreactors.

Depending on the abundance of the *Desulfitobacterium* population in the final enrichment, several approaches may be applied for the successful isolation of pure cultures. The most common techniques include serial dilution to extinction, soft agar shake cultures, or plating on agar media under selective or nonselective growth conditions. Anoxic conditions should be maintained during all steps of the isolation procedure because high levels of oxygen are not tolerated by most strains for longer periods. The further growth requirements of *Desulfitobacterium* strains in pure culture are generally not very fastidious, so that pre-reduced, standard freshwater mineral media supplemented with low amounts of yeast extract (0.1–0.2%) and suitable substrates are in most cases adequate for cultivation. Note, however, that a requirement for vitamin K1 in the growth medium was reported for the *Desulfitobacterium* strain DCA1 (De Wildeman et al., 2003). Isolation media should contain a buffer system (e.g., carbonate-CO_2) to keep the pH at a circumneutral value, especially if halogenated compounds are used as electron acceptors. Otherwise, HCl formed by reductive dechlorination could lead to a decrease of medium pH. Most *Desulfitobacterium* strains are not sensitive to sodium sulfide as a reductant, but several strains belonging to this phylogenetic group are inhibited by high sulfide concentrations in the medium (The Genus *Desulfotomaculum* in this Volume). Therefore, keeping the concentration of sulfide in the medium as low as possible and if necessary using dithionite (15–30 mg/liter) as an additional reductant is recommended. To monitor the redox status of the medium, adding the indicator resazurin prior to autoclaving is useful. Resazurin is pink when the redox potential is above –50 mV and colorless when the redox potential is below –110 mV (i.e., highly reduced conditions). After inoculation, cultures are normally incubated at 30–37°C for 1–5 days in the dark.

Nonselective growth media suitable for the cultivation and maintenance of most *Desulfitobacterium* strains can be found for example in the

Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH (DSMZ; German collection of microorganisms and cell cultures) [{www.dsmz.de/media}{catalogue of strains}]. The procedure for preparing a general-purpose *Desulfitobacterium* medium is given below.

DSMZ Medium 720

NH_4Cl	1.00 g
NaCl	0.10 g
$MgCl_2 \cdot 6H_2O$	0.10 g
$CaCl_2 \cdot 2H_2O$	0.05 g
$K_2HPO_4 \cdot 3H_2O$	0.40 g
Trace element solution (see below)	1.00 ml
Selenite-tungstate solution (see below)	1.00 ml
Resazurin	0.50 mg
Yeast extract	1.00 g
$NaHCO_3$	2.60 g
Vitamin solution (see below)	10.0 ml
Na-pyruvate	2.50 g
$Na_2S_2O_3 \cdot 5H_2O$	1.25 g
$Na_2S \cdot 9H_2O$	0.30 g
Distilled water	1000 ml

Dissolve ingredients (except bicarbonate, vitamins, pyruvate, thiosulfate and sulfide), boil medium for 3 min, and then cool to room temperature under 80% N_2 + 20% CO_2. Add solid bicarbonate and adjust pH to 7.0. Dispense under the same gas mixture in anoxic vessels and autoclave. Add vitamins (sterilized by filtration), pyruvate, thiosulfate and sulfide from sterile, anoxic stock solutions prepared under N_2.

Trace Element Solution

Na_2-EDTA	0.50 g
$FeCl_2 \cdot 4H_2O$	1.50 g
$ZnCl_2$	70.00 mg
$MnCl_2 \cdot 4H_2O$	100.00 mg
H_3BO_3	6.00 mg
$CoCl_2 \cdot 6H_2O$	190.00 mg
$CuCl_2 \cdot 2H_2O$	2.00 mg
$NiCl_2 \cdot 6H_2O$	24.00 mg
$Na_2MoO_4 \cdot 2H_2O$	36.00 mg
Distilled water	990 ml

First dissolve EDTA and adjust pH to 6.5 with KOH, then add minerals. Adjust final pH to 7.0 with KOH.

Selenite-tungstate Solution

NaOH	0.50 g
Na_2SeO_3	3.00 mg
$Na_2WO_4 \cdot 2H_2O$	4.00 mg
Distilled water	1000 ml

Vitamin Solution

Biotin	2.0 mg
Folic acid	2.0 mg
Pyridoxine-HCl	10.0 mg
Thiamine-HCl $\cdot$ 2H$_2$O	5.0 mg
Riboflavin	5.0 mg
Nicotinic acid	5.0 mg
D-Ca-pantothenate	5.0 mg
Vitamin B_{12}	0.10 mg
p-Aminobenzoic acid	5.0 mg
Lipoic acid	5.0 mg
Distilled water	1000 ml

Identification

A definite affiliation of isolates to the genus *Desulfitobacterium* is in most cases possible by the distinguishing characteristics presented in Table 1 (see the section Common Traits and Differentiation in this Chapter). Currently, this genus comprises validly published descriptions of the following five species: *Dba. dehalogenans* (Utkin et al., 1994), *Dba. hafniense* (Christiansen and Ahring, 1996), *Dba. frappieri* (Bouchard et al., 1996), *Dba. chlororespirans* (Sanford et al., 1996), and *Dba. metallireducens* (Finneran et al., 2002). The type species of the genus is *Dba. dehalogenans*. Recently, genomic and phenotypic evidence showed that the type strains of the species *Dba. hafniense* and *Dba frappieri* are very closely related and should be united in one species (Niggemyer et al., 2001). *Desulfitobacterium hafniense* is the oldest legitimate epithet of this taxon and hence *Dba. frappieri* is a later heterotypic synonym of *Dba. hafniense*. Consequently, in the text of this chapter all strains that have been affiliated in the literature to *Dba. frappieri* will be referred to as *Dba. hafniense*, which has priority.

A reliable identification of distinct species within this genus is more complex and requires a profound polyphasic characterization based on phenotypic and molecular methods. The difficulties inherent to the classification of *Desulfitobacterium* strains arise from their metabolic plasticity which prevents a clear cut assignment of isolates to distinct species on the basis of phenotypic characteristics. This is most evident in *Dba. hafniense*. A comparison of the characteristics of strains which were at least tentatively affiliated to this species allows a good estimate of the intraspecific diversity possible in species of this genus. For instance, the *Dba. hafniense* strain DP7 was shown incapable of dehalogenating chlorinated compounds (Van de Pas et al., 2001), whereas strain PCE-S was shown incapable of utilizing sulfite or thiosulfate as electron acceptors (Miller et al., 1998). The lack of these features in *Desulfitobacterium* strains is unexpected because these were thought to represent hallmark traits of this genus. Consequently, molecular methods like the comparative analysis of 16S rRNA gene sequences and DNA-DNA hybridization experiments are necessary for the unambiguous identification of isolates.

A list of distinguishing traits useful for the differentiation of *Desulfitobacterium* species can be found in Table 2.

Morphology

Members of the genus *Desulfitobacterium* have generally a straight to slightly curved rod-shaped

Table 2. Main morphological and physiological characteristics of *Desulfitobacterium* species.

Symbols and abbreviations: Nr, not reported; +, positive in most strains; −, negative in most strains; and D, different reaction among strains; 3-Cl-4-OHPA, 3-chloro-4-hydroxyphenylacetate; and PCE, tetrachloroethene.

Abbreviations: 3-Cl-4-OHPA, 3-chloro-4-hydroxyphenylacetate; and PCE, tetrachloroethene.

[a]The species epithets *Desulfitobacterium hafniense* and *Dba. frappieri* are subjective synonyms (Niggemyer et al., 2001) and hence are considered as one species. Only the strains DCB-2[T], PCP-1, and GBFH were considered in this table because their affiliation to the species *Dba. hafniense* was confirmed by DNA-DNA hybridization.

Data from Utkin et al. (1994), Christiansen and Ahring (1996), Bouchard et al. (1996), Sanford et al. (1996), Dennie et al. (1998), Niggemyer et al. (2001), van de Pas et al. (2001), and Finneran et al. (2002).

morphology. The cell dimensions are 0.5–0.7 μm × 2–6 μm. A phase contrast micrograph of *Dba. dehalogenans* DSM 9161[T] is shown in Fig. 2.

The Gram staining depends on the species and is positive in *Dba. dehalogenans* and *Dba. metallireducens* but negative in *Dba. hafniense* and *Dba. chlororespirans*. To date, ellipsoidal and terminal spores that slightly swell the cell were detected only in *Desulfitobacterium* species that stain Gram negative. In general, the tendency of *Desulfitobacterium* strains to form spores is less pronounced than in cultures of *Desulfosporosinus* species and the frequency of spore-forming cells is low.

Flagellation is variable and strain specific. Most strains are motile by means of polar or lateral flagella, but the type strain of *Dba. metallireducens*, 853-15A[T], and the *Dba. hafniense* strain PCP-1 are nonmotile. Interestingly, the type strain of *Dba. hafniense*, DCB-2[T], is motile by means of 1–2 polar flagella, whereas the *Dba. hafniense* strain GBFH possesses 2–5 lateral flagella.

With the exception of the *Dba. dehalogenans* strain JW/IU-DC1[T], all described strains form colonies on solid agar media. Colonies on agar surfaces are white, translucent, circular to slightly irregular and smooth. They reach several mm in diameter.
Fig. 2. Phase contrast micrograph of *Dba. dehalogenans* DSM 9161[T]. Bar = 10 μm.

Physiology and Chemotaxonomy

In Table 2, several physiological characteristics helpful for the differentiation of *Desulfitobacterium* species are listed.

A comparison of whole cell fatty acid patterns of the type strains of the genus *Desulfitobacterium* can be found in Table 3. In general, the fatty acid patterns of representatives of this genus are rather complex and comprise several compounds that were not identified by the MIDI system (Microbial ID, Inc., Newark, DE). The following fatty acids were found to be dominating in most strains: 14:0, 16:1 *cis*9, 16:0, and 18:1 *cis*11. The fatty acid patterns of the *Dba. hafniense* strains DSM 10664[T] and DSM 12420 (formerly representing *Dba. frappieri*) were very similar, whereas the patterns of the phylogenetically distinct species *Dba. dehalogenans* and *Dba. metallireducens* are clearly different. Hence, a differentiation of species within this genus by means of fatty acid patterns seems to be possible. In *Dba. dehalogenans* the three characteristic fatty acids are 16:0, 14:0, and 16:1 *cis*9; in *Dba. hafniense* 18:1 *cis*11 dma, 18:1 *cis*11, and 16:1 *cis*9; in *Dba. chlororespirans* 16:0, 16:1 *cis*9, and 14:0; and in *Dba. metallireducens* 14:0, 16:1 *cis*9 dma, and an unidentified fatty acid with an equivalent chain length (ECL) of 13.52.

Molecular Methods

The determination and comparative analysis of 16S rRNA gene sequence data is a valuable method for the identification of *Desulfitobacterium* isolates. Studies on several *Dba. hafniense* strains have clearly shown that methods based on the analysis of DNA are more reliable for the affiliation of strains to distinct *Desulfitobacterium* species than physiological or biochemical tests (Van de Pas et al., 2001). However, the diversity of multiple 16S rRNA operons in *Desulfitobacterium* strains caused in the past some confusion about their correct phylogenetic placement. In the *Dba. hafniense* strains PCP-1 (Lévesque et al., 1997) and GBFH (Niggemyer et al., 2001) at least three distinct rRNA operons could be detected. The various 16S rRNA operons of *Desulfitobacterium* strains can differ by the size of an insert between nucleotide position 75 and 94 (*Escherichia coli* numbering). The standard size of this region is 22 nucleotides, but in distinct operons it can reach 139 nucleotides (Van de Pas et al., 2001). The presence of multiple operons among *Desulfitobacterium* species was overlooked for several years because of the cloning of PCR products leading to the subsequent sequencing of just one 16S rRNA gene. In contrast, the direct sequencing of amplified 16S rRNA gene fragments, which is now a standard method, often reveals multiple operons by clearly defined unreadable regions which are caused by overlapping sequence stretches. To avoid a bias in the reconstruction of phylogenetic trees it is advisable to completely remove the 5' terminal hypervariable region of *Desulfitobacterium* 16S rRNA gene sequences (*E. coli* positions 1 to 94) prior to the calculation of distance matrices. A phylogenetic dendrogram illustrating the intrageneric relationship of most known *Desulfitobacterium* strains is shown in Fig. 3.

In Fig. 3, the large number of strains which can be affiliated to the species *Dba. hafniense* is shown. All strains within this cluster share 16S rRNA sequence similarity values (*E. coli* nucleotide positions 95–1521) above 99%. The affiliation of the strains PCP-1 (formerly *Dba. frappieri*) and GBFH to the species *Dba. hafniense* was confirmed by DNA-DNA hybridization experiments with the type strain DCB-2[T] (Niggemeyer et al., 2001). DNA-DNA hybridization data exist also for the two *Dba. hafniense* strains TCE1 and DP7 (83%; Van de Pas et al., 2001).

On the other hand, DNA-DNA binding values of *Dba. hafniense* DCB-2[T] with the phylogenetically distinct strains *Dba. chlororespirans* Co23[T] and *Dba. dehalogenans* JW/IU-DC-1[T] were only 64.3% and 43.9%, respectively (Niggemyer et al., 2001). The threshold value for strains belonging to one species is 70% (Wayne et al., 1987).

Hence, a comparison of both genetic approaches within this clade of bacteria justifies the conclusion that strains which share 16S rRNA sequence similarity values above 99% probably belong to the same species, whereas values below 98% clearly indicate the affiliation of strains to separate species. However, this assumption is restricted to the known *Desulfitobacterium* strains and may not holds true for other taxa.

[a]The strains DSM 9161[T], DSM 10664[T], DSM 12420[T], and DSM 11544[T] were grown in DSM medium 720 for 24h prior to analysis, whereas DSM 15288[T] was cultured in DSM medium 838 for 48h.
[b]Unknown fatty acids could not be identified with the Microbial Identification (Microbial ID) standard software package (Sasser, 1990).
[c]Data are percent total fatty acids. The three most dominating fatty acids of each strain are in bold. Fatty acids that were detected only in trace amounts (<0.5%) in all analyzed strains were not considered in this table.

The automated RiboPrinter system (DuPont Qualicon) offers a fast and reliable approach for the identification of *Desulfitobacterium* strains by analysis of genomic DNA (Bruce, 1996). In Fig. 4, riboprint patterns of all *Desulfitobacterium* type strains generated with the restriction enzyme *Eco*RI are shown. The resulting riboprints were specific for each tested strain. The riboprints of the *Dba. hafniense* strains DSM 10664[T] and DSM 12420 (formerly representing *Dba. frappieri*) were most similar, but clearly distinct from all other patterns. Consequently, the diversity of patterns correlated well with the phylogenetic relationships of these strains.

For the detection of *Desulfitobacterium* species in the environment, specific PCR primers were developed on the basis of 16S rRNA gene sequences. Specific primer sets enabling nested

PCR were designed for *Dba. dehalogenans* (Fantroussi et al., 1997) and *Dba. hafniense* (formerly *Dba. frappieri*; Lévesque et al., 1997). The amplification of *Desulfitobacterium* DNA with the primer sets binding to the terminal regions of the 16S rRNA genes results in PCR fragments with a size of 1199 nucleotides in *Dba. dehalogenans* and 1080 nucleotides in *Dba. hafniense*. The obtained PCR products can be used as template for the amplification of internal fragments in a second round PCR reaction. By application of the nested PCR approach, the sensitivity for the detection of *Desulfitobacterium* cells in soil could be increased several times compared to the one-step PCR. The detection limit under optimal conditions was approximately 10^3 cells/g of soil. A further advantage of the nested PCR approach is that the risk of false positive signals is reduced. This approach was successfully used for the monitoring of *Desulfitobacterium* cells in laboratory

enrichment cultures or soil (Lanthier et al., 2000; Lanthier et al., 2001).

An interesting alternative procedure for the detection of *Desulfitobacterium* cells in the environment was presented by Christiansen and Ahring (1996). They derived calibrated antibody probes from rabbit antisera against *Dba. hafniense* DCB-2^T. Cells which have bound the specific antibody could be visualized by indirect immunofluorescence. The advantage of this method is that a direct count of cells in environmental samples is possible. However, a careful control of the specificity of the antibody has to be performed to avoid false positive signals by crossreactivity, a frequently encountered problem in the application of specific antibodies.

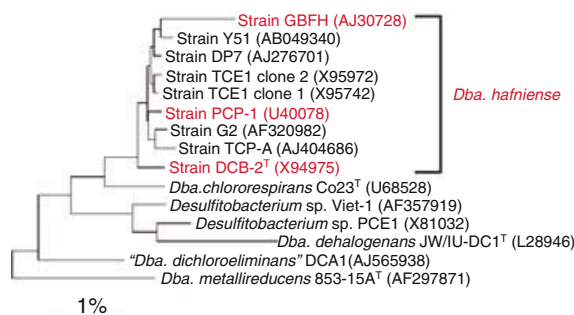
A further method for the direct visualization of single cells in environmental samples was developed by Lanthier et al. (2002). They designed specific fluorescently labelled oligonucleotide probes targeting distinct regions of the respective 16S rRNA molecules of *Desulfitobacterium. hafniense* and *Dba. chlororepirans*. With this method the intensity of the hybridization signal depends largely on the intracellular content of ribosomal RNA. Consequently, this has the advantage that only metabolically active cells are detected using epifluorescence microscopy, while resting cells remain unseen owing to their low content of ribosomal RNA.


Fig. 3. Phylogenetic dendrogram based on partial 16S rRNA gene sequences (nucleotides 95 to 1521, *E. coli* numbering) showing the intrageneric relationship of *Desulfitobacterium* strains. Strains for which the affiliation to the species *Dba. hafniense* was confirmed by DNA-DNA hybridization are shown in red. The GenBank/EMBL accession number for each sequence is shown in parenthesis. The tree was reconstructed using the ARB program package (http://www.arbhome.de). It is derived from a distance matrix reconstructed by using the neighbor joining method of Saitou and Nei (1987). Phylogenetic distances were calculated as described by Felsenstein (1982). The sequence of *Desulfosporosinus orientis* (accession no. [Y11570]) was used to define the root (not shown). Scale bar represents 1% estimated sequence divergence.

Preservation

Stock cultures of most *Desulfitobacterium* strains can be kept for about one month at 4°C without loss of viability. For the intermediate storage of cultures, freezing in anoxic medium supplemented with 50% glycerol may be suitable. However, for the long-term storage, lyophilization is recommended. Some *Desulfitobacterium* strains may be sensitive to the freeze drying process and display low survival rates after lyophilization. For the long-term preservation of these strains, freezing in liquid nitrogen is a suitable method using suspensions of cells in freshly prepared medium supplemented with 5% of the cryoprotectant dimethyl sulfoxide (DMSO). Detailed descriptions for the lyophilization and deep

Fig. 4. Diversity of riboprint patterns of *Desulfitobacterium* type strains generated with *Eco*RI. The similarity dendrogram was generated using Bionumerics software (Applied Maths).
freezing of anaerobes can be found in the contribution of Hippe (1991).

The Genus *Desulfosporosinus*

Habitat

Members of the genus *Desulfosporosinus* were mainly isolated from water-saturated soil environments and freshwater sediments that are usually anoxic. The *Desulfosporosinus* strain 343 (DSM 8344) was isolated from permafrost deposits of an ancient river bed in Kolymskaya Lowland, Russia. Presumably, the cells of this strain were not active in situ but survived in the form of spores for a few thousand years in the permafrost soil (Vainshtein et al., 1995).

Isolation

In cultures of many *Desulfosporosinus* strains, a significant number of sporeforming cells is frequently observed. The formation of heat-resistant endospores makes it possible to use essentially the same selective enrichment and isolation procedures and media for these strains as described for sporeforming sulfate reducers of the genus *Desulfotomaculum* (The Genus *Desulfotomaculum* in this Volume). If necessary, nonsporeforming sulfate reducers which frequently outcompete members of the genus *Desulfosporosinus* in samples of permanently anoxic habitats can be eliminated by pasteurization of samples at 80°C for 10–20 min.

The species *Dsp. auripigmenti* was selectively enriched from a mixed culture of sulfate reducers obtained from a contaminated lake sediment by replacing sodium sulfate with 10 mM dibasic sodium arsenate as electron acceptor in the used freshwater mineral medium. Lactate (20 mM) served as carbon and energy source and cysteine was used as reducing agent and source of reduced sulfur. Growth and subsequent reduction of arsenate became visible by the formation of a yellow precipitate, determined to be As_2S_3 (Newman et al., 1997). A purification of the isolate responsible for arsenate reduction was achieved by successive colony transfers in agar shake tubes.

Most strains of *Desulfosporosinus*, however, were enriched and isolated under nonselective growth conditions by serial dilution of samples of anoxic soil or sediment in agar deeps or liquid media. For the purification of isolates, serial dilution to extinction, soft agar shake cultures, or plating on agar media are suitable methods. Anoxic conditions should be maintained during all steps of the isolation procedure because high levels of oxygen are not tolerated by vegetative cells of *Desulfosporosinus* for longer periods. For

the same reason, media used for isolation should be pre-reduced. Suitable reductants are sodium sulfide, cysteine, ascorbate and thioglycollate, or sodium dithionite. *Desulfosporosinus orientis* among other Gram-positive sporeforming sulfate reducers occasionally shows poor growth in media that have been reduced with sodium sulfide. Certain impurities in the commercially available Na_2S likely have an inhibitory effect on the growth of these strains (The Genus *Desulfotomaculum* in this Volume). For the cultivation of these microorganisms, alternative reductants should be used or the amount of sulfide should be reduced to a minimum. If a low amount of sulfide is used (<100 mg/liter), the addition of 10–20 mg of sodium dithionite per liter of medium shortly before inoculation (e.g., from a 5% [w/v] solution, freshly prepared under N_2, and filter-sterilized) often stimulates growth of sulfate reducers at the beginning.

All known members of this genus grow well and occasionally sporulate in the DSMZ medium 641 DSMZ catalogue of strains (http://www.dsmz.de/media) which has been modified by replacing malate and pyruvate with sodium lactate (2.5 g/liter). The procedure for preparing this medium is given below.

Modified DSMZ Medium 641

NH_4Cl	1.0 g
Na_2SO_4	2.0 g
Na-thiosulfate · $5H_2O$	1.0 g
$MgSO_4$ · $7H_2O$	1.0 g
$CaCl_2$ · $2H_2O$	0.1 g
KH_2PO_4	0.5 g
Resazurin	0.5 mg
Trace element solution	
(see *Desulfitobacterium* medium above)	1.0 ml
Yeast extract	1.0 g
Na-lactate	2.5 g
$NaHCO_3$	2.0 g
Vitamin solution	
(see *Desulfitobacterium* medium above)	10.0 ml
Na_2S · $9H_2O$	75.0 mg
Distilled water	1000 ml

Dissolve ingredients (except bicarbonate, vitamins and sulfide), boil medium for 3 min., and then cool to room temperature under 100% N_2. Dispense medium under N_2 gas atmosphere in tubes or bottles and autoclave. Complete the medium by adding vitamins (sterilized by filtration), sulfide (from sterile, anoxic stock solutions prepared under N_2) and bicarbonate (from a sterile, anoxic stock solution prepared under 80% N_2 and 20% CO_2). Adjust pH of the completed medium if necessary to about 7.0–7.2.

Identification

The genus *Desulfosporosinus* is well defined on the basis of physiological and chemotaxonomical traits. However, a differentiation from other genera of Gram-positive, sporeforming sulfate

reducers, especially *Desulfotomaculum* species, is often not unambiguously possible on the basis of a physiological characterization. For instance, both species *Desulfotomaculm ruminis* and *Desulfosporosinus orientis* are morphologically and nutritionally very similar but phylogenetically only distantly related. Thus, a reliable identification of isolates should always be preceded by a phylogenetic analysis of DNA sequence data. The genus *Desulfosporosinus* comprises currently three different species: *Dsp. orientis* (Campbell and Postgate, 1965; Stackebrandt et al., 1997), *Dsp. meridiei* (Robertson et al., 2001), *Dsp. auripigmenti* (Newman et al., 1997; Stackebrandt et al., 2003).

The type species of the genus is *Dsp. orientis*, which currently includes three different strains. However, the description of this taxon is exclusively based on the type strain Singapore I[T] (DSM 765[T]). The mesophilic strain 343 (DSM 8344) isolated from ancient permafrost soil in Russia was classified by Vainshtein et al. (1995) as *Dsp. orientis* solely on the basis of a phenotypic characterization. Recently published phylogenetic data based on 16S rRNA gene sequence information (R. F. Rosenweig et al., unpublished results) and DNA-DNA hybridization experiments (Stackebrandt et al., 1997) are contradictory to this assumption and clearly indicate that strain 343 represents a novel species within the genus *Desulfosporosinus*. In contrast, the identification of strain Ulu Singapore II (DSM 7439) as *Dsp. orientis* is supported by 16S rRNA gene sequence analysis and the high similarity between riboprint patterns of this strain and the type strain Singapore I[T] (Stackebrandt et al., 2003). However, for the definite affiliation to *Dsp. orientis*, a DNA-DNA hybridization experiment with the type strain would be necessary. Likewise, *Desulfosporosinus* the description of auripigmenti, is based only on a single strain. Consequently, the intraspecific diversity (which can be expected among species of this genus) could be only studied with strains of one species. A knowledge of the possible intraspecific variability within a genus is important to estimate the value of distinct taxonomic traits for the identification of species. In general, the phenotypic variability of a taxon depends on the range of genomic diversity within clonal populations composing this taxon. Variable traits of *Dsp. meridiei* include nitrate reduction (3 out of 7 strains, type strain negative) and utilization of formate (3 out of 7 strains, type strain positive), caproate (1 out of 7 strains, type strain negative), caprylate (4 out of 7 strains, type strain negative), methanol (2 out of 7 strains, type strain positive), and syringic acid (3 out of 7 strains, type strain positive).

A list of distinguishing traits useful for the differentiation of *Desulfosporosinus* species can be found in Table 4.

Morphology

Cells representing *Desulfosporosinus* strains are generally described as slightly bent or curved rods ("sausage-shaped"). The cells are 0.4–1.2 µm × 2.5–5.5 µm. Occasionally, long filament-like cells are observed. Large rods are often flexible and display a snake-like twisting motility often without forward motion.

Almost all *Desulfosporosinus* strains stain Gram-negative or Gram-variable, but *Dsp. auripigmenti* stains Gram-positive. The cytoplasm of cells in aged cultures of *Dsp. orientis* may sometimes appear granulated because of the formation of phase-dense inclusion bodies. The strains of all described species form ellipsoidal spores that slightly swell the cell (Fig. 5a). Spores are located mainly at a subterminal position; in *Dsp. auripigmenti*, frequently also terminal. The unclassified strain 343 (DSM 8344) stains Gram positive and exhibits spherical spores located at a terminal position.

An active swimming motility is in several strains restricted to the early logarithmic growth phase. In the first description of *Dsp. orientis* by Adams and Postgate (1959), the French bacteriologist A. Prevot is cited as the scientist who analyzed the flagellation type of this species. Prevot found that (sub)polar or bipolar flagellation was predominant, and cells that appeared peritrichously flagellated were rare and may represent pairs or chains of cells with bipolar flagella (". . . la forms la plus fréquent est le cil unique polaire ou para-polaire. Puis vient en deuxième position la ciliature bipolaire, enfin moins fréquent la ciliature en apparence péritriche 3 à 4 cils. Mais si on analyse minutieusement les formes à 3 ou 4 cils on s'aperçoit que ce sont des diplo-vibrions ou des chainettes de vibrions"). In a later published description of this species by Campbell and Postgate (1965), only a peritrichous flagellation type was mentioned, which is inconsistent with the early investigation of Prevot. To clarify this point the flagellation type of this strain was examined by one of the authors (SS). At a first look it actually appears that several flagella are randomly distributed on the cell surface of this strain. However, at a closer examination most cells have either lateral or subpolar to polar flagella, whereas a truly peritrichous flagellation type could not be detected (Fig. 5b). The number of flagella per cell may change with the age of the culture inasmuch as far more cells have single polar or bipolar flagella in stationary phase cultures than in young cultures, which predominantly contain cells with lateral flagellation.

Table 4. Main morphological and physiological characteristics of *Desulfosporosinus* species.

Characteristic	Dsp. orientis	Dsp. meridiei	Dsp. auripigmenti

[a]Data are solely based on the type strain Singapore I[T] (DSM 765[T]).

[b]If the reaction was variable among the tested strains, the result for the type strain is given in parenthesis.

Data from Campbell and Postgate (1959), Klemps et al. (1985), Newman et al. (1997), Robertson et al. (2001), and Stackebrandt et al. (2003).
Fig. 5. Morphological characteristics of *Desulfosporosinus* species. (a) Phase contrast micrograph of a sporulating culture of *Dsp. auripigmenti* DSM 13351[T]. Bar = 10 μm. (b) Typical flagellation pattern of *Dsp. orientis* DSM 765[T] visible after staining according to the protocol of Heimbrook et al. (1989). Bar = 10 μm.

Strains of *Dsp. meridiei* are motile by means of a single subpolar or lateral flagellum. The type strain of *Dsp. auripigmenti* was described as nonmotile.

Physiology and Chemotaxonomy

Table 4 lists physiological characteristics of *Desulfosporosinus* species and Table 5 lists whole cell fatty acid patterns of the type strains of *Desulfosporosinus* species.

Compared to the fatty acid patterns of *Desulfitobacterium*, those of *Desulfosporosinus* strains are in general less complex and the variability among distinct species is less pronounced. The predominant fatty acids in most strains were 16:1 *cis*9, 16:0, and 16:0 dma. Fatty acid patterns of the type strains of *Dsp. orientis* and *Dsp. auripigmenti* were quite similar, whereas a differentiation from *Dsp. meridiei* may be possible by the low amount of the fatty acid 16:0.

A useful chemotaxonomic marker for the differentiation of *Dsp. idahoensis* from other *Desulfosporosinus* species is the detection of *meso*-diaminopimelic acid. This diamino acid has so far been detected in only the cell wall pepti-

doglycan of *Dsp. idahoensis*, whereas LL-Dpm was found to predominate in all other species of this genus.

Molecular Methods

The method of choice for the definite affiliation of isolates to the genus *Desulfosporosinus* is the determination and comparative analysis of 16S rRNA gene sequences, whereas an unambiguous identification at the species level is hardy possible solely on the basis of 16S rRNA gene sequence data. Large insertions or deletions in distinct operons of 16S rRNA genes, as found in *Desulfitobacterium* strains, were so far not detected in members of the genus *Desulfosporosinus* by the direct sequencing of PCR products. Nevertheless, the presence of multiple operons differing only by single base exchanges cannot be completely excluded since minor variations in 16S rRNA genes are not reliably detected by this approach and other methods for the detection of multiple operons have not up to now been applied to this genus. The limited value of 16S rRNA gene sequencing for the identification of *Desulfosporosinus* species is illustrated by the fact that both *Dsp. lacus* and *Dsp. idahoenis* possess almost identical 16S rRNA genes sharing a similarity value of 99.7%. Interestingly, both species were isolated from different environments and geographical sites and can be easily distinguished on the basis of phenotypic or chemotaxonomic traits. In addition, the delineation between both type strains was confirmed by a DNA-DNA binding value below 70% (63%) and clearly different riboprint patterns (In Figure 6 it is two strains of *Dsp. orientis*, DSM 765[T] and DSM 7439, with 99.7% 16S rRNA gene similarity, show similar riboprint patterns to the type strain shown that STP12 representing the tentatively novel species "Desulfosporosinus lacus", which has only 96.4% similarity to the type strain of *Dsp. orientis*. Consequently, neither 16S rRNA gene sequencing nor ribotyping alone are suitable approaches for the reliable identification of *Desulfosporosinus* species. On the other hand, the taxonomic status of the remaining *Desulfosporosinus* type strains and the separate position of the strain DSM 8344 was confirmed by DNA-DNA hybridization experiments and individual riboprint patterns (Robertson et al., 2001; Stackebrandt et al., 2003).

Preservation

The procedures for maintaining and preserving *Desulfosporosinus* strains are similar to the methods described for *Desulfitobacterium*. In

Table 5. Fatty acid compositions of the type strains of *Desulfosporosinus* species.

addition, the pronounced tendency of some *Desulfosporosinus* strains to form spores enables the maintainance of cultures in the sporulated state (optimally as deep agar colonies). Sporulated cultures are usually stable for several months at temperatures around 4°C. The DSMZ medium 641 is suitable for the induction of sporulation in most strains. The sporulation in *Dsp. orientis* can be efficiently induced if this species is grown under sulfate limitation with hydrogen as electron donor (Cypionka and Pfennig, 1986).

CHAPTER 1.2.25

The Genus *Desulfotomaculum*

FRIEDRICH WIDDEL

A summary of the diversity and biochemistry of bacteria that carry out a dissimilatory sulfate reduction has been given in Chapter 24. Sulfate-reducing bacteria that form heat-resistant endospores are classified in one genus, *Desulfotomaculum* (Campbell and Postgate, 1965). The first isolate of this genus, a moderate thermophile, was originally described as *Clostridium nigrificans* (Werkman and Weaver, 1927), later as *Sporovibrio desulfuricans* (Starkey, 1938), and finally was named *Desulfotomaculum nigrificans* (Campbell and Postgate, 1965). Subsequently, some other moderately thermophilic and some mesophilic *Desulfotomaculum* species were isolated (Table 1). The genus exhibits a great nutritional versatility, comparable to that of nonsporeforming sulfate reducers (see Chapter 24). H_2, alcohols, fatty acids, other aliphatic monocarboxylic or dicarboxylic acids, alanine, hexoses, or phenyl-substituted organic acids may be used as electron donors for dissimilatory sulfate reduction (Table 1). Utilization of polysaccharides or polypeptides has not been reported.

Figures 1 and 2 show morphological features of a few *Desulfotomaculum* species. They are true Gram-positive bacteria and thus phylogenetically separate from other sulfate-reducing eubacteria, as is evident from their cell wall structure (Nazina and Pivovarova, 1979; Sleytr et al., 1969; Fig. 2B) and from 16S rRNA analyses (Devereux et al., 1989; Fowler et al., 1986). *Desulfotomaculum* species cluster with the branch of Gram-positive bacteria with DNA of low GC content (Fig. 3). *Desulfotomaculum* species may be regarded as clostridia-like bacteria which have the additional capacity for dissimilatory sulfate reduction.

Habitats

Sporeforming sulfate reducers thrive essentially in the same habitats as nonsporeforming types. However, *Desulfotomaculum* species have been isolated less frequently than Gram-negative sulfate reducers from habitats that are permanently or usually anoxic. In these environments, sporeforming species are apparently less competitive than nonsporeforming ones. In contrast, if conditions are prevailing that are selective for bacteria with spores, *Desulfotomaculum* species appear to be the predominant sulfate reducers in the particular environment. In contrast to nonsporeforming sulfate reducers, because of its spores, *Desulfotomaculum* is able to survive dryness and oxic conditions for many months or even years. If the conditions turn again anoxic, *Desulfotomaculum* species are the first sulfate reducers to develop. Such a selection for *Desulfotomaculum* has been observed in rice paddies where oxic and anoxic conditions alternate due to seasonal flooding. Anoxic samples collected during the flooding period from the rhizosphere of rice contained *Desulfotomaculum* as the predominant sulfate reducer (V. A. Jacq, personal communication). Also, in some other cases, the source of isolation reflected the survival of *Desulfotomaculum* species as spores. *D. nigrificans* was found in canned food (Werkman and Weaver, 1927), and *D. orientis* (Adams and Postgate, 1959) and *D. sapomandens* (Cord-Ruwisch and Garcia, 1985) originate from soil. Actually, spores of lactate- or fatty acid-oxidizing *Desulfotomaculum* species are regularly detected in oxic humid or dry soil, even if it has never been anoxic (F. Widdel, unpublished observations). Spores are probably spread by wind or animals and remain viable for years.

In contrast to sulfate-reducing bacteria of the gamma subdivision, the genus *Desulfotomaculum* contains a number of moderately thermophilic species with temperature optima of 54 to 65°C (Table 1). A *D. nigrificans* strain was isolated from hot-oil-field water (Nazina and Rozanova, 1978). *D. geothermicum* and *D. kuznetsovii* were obtained from geothermal ground water, and *D. thermoacetoxidans* originated from a thermophilic biogas fermenter. Hence, sulfate reduction in habitats with temperatures between 50 and 65°C can mainly be due to *Desulfotamaculum* species. However, at temperatures above 60 to 65°C, *Thermodesulfobacterium* species may

[d]Symbols: +, utilized; +*, autotrophic growth; (+), poorly utilized; –, not utilized; ND, not determined.
[e]Not completely listed; for further substrates, see references.
[f]Symbols: bi, biotin; pa, *p*-aminobenzoate.
[g]Type strain does not require NaCl. Another strain requires 5 g NaCl per liter for optimum growth (Nazina and Rozanova, 1978).

also play a role; however, they cannot oxidize acetate or fatty acids that are utilized by part of the thermophilic *Desulfotomaculum* species. If dissimilatory sulfate reduction occurs at temperatures of around 80°C or higher, this is probably due to archaebacterial sulfate reducers (see The Genus *Archaeoglobus* in Volume 3).

Most *Desulfotomaculum* species that have been described grow best at low salt concentrations and thus seem to be dwellers mainly of freshwater habitats or other aqueous environments with relatively low salt concentrations. However, *D. geothermicum* isolated from saline geothermal ground water, grew optimally with 20 to 30 g NaCl per liter (Daumas et al., 1988). A *D. nigrificans* strain from hot-oil-field water

required 5 g NaCl per liter for optimum growth (Nazina and Pivovarova, 1979). Two other, unnamed types that were probably adapted to a saline environment were a benzoate-utilizing strain from an oil field (Cord-Ruwisch et al., 1986) and an acetate-utilizing strain from marine sediment (Keith et al., 1982).

D. ruminis has been isolated from sheep rumen (Coleman, 1960). However, with 10^2 cells/ml, this type was present in far lower numbers than *Desulfovibrio*, which exhibited an abundancy of 10^7 cells/ml (Howard and Hungate, 1976). *Desulfotomaculum acetoxidans* could be readily and repeatedly enriched from animal manure with butyrate as energy source (Widdel and Pfennig, 1977, 1981; F. Widdel, unpublished observations).

Cultivation Techniques and Media

For cultivation of *Desulfotomaculum* species, the same vessels, equipment, and anoxic techniques as described in detail for Gram-negative sulfate reducers (see Chapter 183) may be used. However, the choice of the reductant can be critical and needs special attention.

Use of Reductants

Desulfotomaculum nigrificans, *D. orientis*, *D. ruminis*, and some other incompletely oxidizing species that were originally isolated on the lactate medium with ascorbate and thioglycollate as reductants (see Gram-Negative Mesophilic Sulfate-Reducing Bacteria in the second edition.) show very poor growth in media reduced with commercial sodium sulfide (Klemps et al., 1985; F. Widdel, unpublished observations). The inhibition by Na₂S is probably not due to sulfide itself, since the added concentration (around 1.5 mM) is far below the concentration that is usually inhibitory to *Desulfotomaculum* species (7 to 10 mM; e.g. Coleman, 1960; Cord-Ruwisch and Garcia, 1985). It is more likely that certain impurities in the commercial sodium sulfide are inhibitory.

The indicated *Desulfotomaculum* species are therefore grown in the lactate medium for *Desulfovibrio*, which is prereduced with ascorbate and thioglycollate. Alternatively, the defined

multipurpose medium (Gram-Negative Meso-philic Sulfate-Reducing Bacteria in the second edition) may be used if ascorbate and thioglycol-late are added instead of Na$_2$S. Bicarbonate/CO$_2$, various vitamins, and trace elements present in the multipurpose medium may be required by several species.

Dithionite has also been used as sole reductant for cultivation of *Desulfotomaculum* species (e.g., Cypionka and Pfennig, 1986). Even though some *Desulfotomaculum* species may be less sensitive toward this reducing agent than other anaerobes, dithionite is probably toxic if added at the same concentration as other reductants. It is therefore added immediately before inocula-tion and only in the smallest amount sufficient to reduce the medium. To assess the redox status, an indicator such as resazurine is added (from a 0.1% (wt/vol) solution of resazurine (sodium salt), 1 ml is added per liter of medium). Sodium dithionite is added from a fresh solution prepared under N$_2$ or as dry powder (Gram-Negative Mesophilic Sulfate-Reducing Bacteria in the sec-ond edition) until resazurine is decolorized. Then, the culture vessel is inoculated and imme-diately sealed, either with a screw cap (in case of completely filled culture vessels) or with a stop-per (in case of vessels with an anoxic head space).

Desulfotomaculum ruminis was isolated in sulfite agar and shown to tolerate sulfite up to a concentration of several mM. Even though the use of Na$_2$SO$_3$ as reductant is not very common, it should be considered for new media for *Desulfotomaculum*.

Desulfotomaculum guttoideum and species using fatty acids have been isolated in Na$_2$S-reduced media and can therefore be grown with this reductant. However, growth in the afore-mentioned media with other reductants may be also attempted. If Na$_2$S is used, dithionite (15 to 30 mg/l) as an additional reductant often signifi-cantly favors initial growth (Widdel and Pfennig, 1977, 1981).

Other Variations of Standard Media

A nonchelated trace element solution such as the solution 1 described in Chapter 183 has been used for cultivation of many *Desulfotomaculum* species (Cord-Ruwisch and Garcia, 1985; Dau-mas et al., 1988; Gogotova and Vainshtein, 1983; Widdel and Pfennig, 1977, 1981). Furthermore, trace elements chelated with EDTA (ethylenedi-aminetetracetic acid, neutralized) or NTA (nitrilotriacetic acid, neutralized) have been used. The EDTA-containing solution (Nazina et al., 1988) had essentially the composition of solu-tion 2. In case of NTA, the composition was as in solution 1, but with 12.8 g NTA (Cypionka and

Pfennig, 1986), or as in solution 3, but with only 4.5 g NTA (Min and Zinder, 1990).

An excellent organic substrate for rapid growth of incompletely oxidizing, lactate-utilizing *Desulfotomaculum* species is pyruvate. Only half as much H$_2$S is formed per mol of pyruvate oxidized to acetate, as per mol of lac-tate oxidized. Therefore, high cell densities can be reached on pyruvate before H$_2$S becomes inhibitory. A stock solution of 2 M pyruvate is prepared from the sodium salt (22 g in 100 ml) or from the cheaper free acid. In the latter case, 14.4 ml (17.6 g) pyruvic acid is added to 40 ml distilled H$_2$O. Then, the solution is neutralized by slow addition of 4 M NaOH and finally of 1 M NaOH under stirring in an ice bath. H$_2$O is added to a final volume of 100 ml. The sodium pyruvate solution is filter-sterilized and stored in the dark at 4°C. Per liter of medium, 15 to 20 ml pyruvate solution are added.

Desulfotomaculum nigrificans does not grow well in defined medium; this species is signifi-cantly stimulated by yeast extract that is present in the lactate medium (Gram-Negative Meso-philic Sulfate-Reducing Bacteria in the second edition). If the multipurpose medium is used, yeast extract is added at the same concentration (1 g/l). A somewhat weaker but distinct stimula-tion in the multipurpose medium was also achieved with a mixture of 60 mg alanine, 90 mg asparagine, 15 mg cysteine, and 85 g threonine instead of yeast extract per liter of medium, and a threefold increased FeSO$_4$ concentration (F. Widdel, unpublished observations). Growth of other incompletely oxidizing *Desulfotomaculum* species is also promoted by yeast extract, but the effect is less pronounced that in the case of *D. nigrificans*. Yeast extract has no effect on the growth of *D. acetoxidans*.

Enrichment, Isolation, and Maintenance

Enrichment

The formation of heat- and drought-resistant spores in *Desulfotomaculum* species allows selective enrichment in the presence of other sulfate reducers. To eliminate nonsporeformers, samples from sediments or other anoxic habitats are pasteurized at 80°C for 10 to 20 min. To guarantee uniform heating, the sample volume is kept small (<10 ml). Pasteurization may be car-ried out in test tubes or bottles incubated in a thermostated water bath. Exclusion of air is not necessary.

Selective enrichment of *Desulfotomaculum* species is also possible from samples of oxic surface soil (see "Habitats," this chapter). Since

nonsporeforming sulfate reducers are usually absent from such soil, *Desulfotomaculum* species are selectively enriched even from nonpasteurized soil samples.

In enrichments with nonpasteurized samples from organic-rich, anoxic habitats (sediments, sludge), *Desulfotomaculum* species are usually outcompeted by nonsporeforming sulfate reducers. An exception seem to be enrichments under moderately thermophilic conditions (50 to 60°C), which often yield *Desulfotomaculum* species even without preceding pasteurization. This is probably due to the lack of nonsporeforming sulfate reducers adapted to this temperature range in these kinds of habitats (see "Habitats," this chapter).

Besides temperature, selective factors for enrichment of various types of *Desulfotomaculum* include the electron donor and the salt concentration. *D. ruminis*, *D. orientis*, and nutritionally similar incomplete oxidizers may be enriched with lactate. Enrichment with an H_2/CO_2 mixture in the presence or absence of some acetate (1 mM) has not been tested but may be also successful. There is, however, no one method that guarantees selection of a particular species. Only *Desulfotomaculum acetoxidans* could be regularly enriched from cow or pig manure with acetate, butyrate, or isobutyrate as electron donors, even without preceding pasteurization (Widdel and Pfennig, 1977, 1981; F. Widdel, unpublished observations).

Various types of sporeforming sulfate reducers may be also obtained by serial dilution of soil or pasteurized mud samples in agar deeps (see below and Gram-Negative Mesophilic Sulfate-Reducing Bacteria in the second edition).

Isolation

Desulfotomaculum species are isolated via serial dilutions in agar deeps or using one of the other procedures described in Chapter 183.

Maintenance

Like many sporeforming bacteria, vegetative cells of *Desulfotomaculum* species die off very soon after growth has ceased, especially if kept at optimal temperature. Many species that grow well lose their viability within 2 to 4 days. Since spores are usually not formed in cultures growing under optimal conditions, strains are easily lost upon prolonged incubation. The rate of cell death may be reduced by growth at suboptimal temperature (e.g., 20°C). However, the best method for preservation of *Desulfotomaculum* cultures is in the sporulated state. Spore formation is often induced in colonies in agar deeps. Strains to be maintained are therefore diluted in agar as described for isolation of pure cultures (see

Gram-Negative Mesophilic Sulfate-Reducing Bacteria in the second edition). Agar tubes with fully grown colonies are incubated for several more weeks to allow completion of sporulation.

Formation of some spores in cultures of *Desulfomaculum acetoxidans* may also occur during slow growth on acetate at suboptimal temperature (20°C). This species never forms spores on butyrate, the preferred substrate for rapid germination of spores and for growth (Widdel and Pfennig, 1981).

Desulfotomaculum orientis forms spores if grown in sulfate-limited cultures with H_2 as electron donor (Cypionka and Pfennig, 1986; Fig. 1B).

Agar tubes with spore-containing colonies are refrigerated. For revival, colonies are picked and transferred to fresh liquid medium. Sporulated liquid cultures may be freeze-dried with skim milk or with the precipitated ferrous sulfate formed in the iron-rich lactate medium B (Gram-Negative Mesophilic Sulfate-Reducing Bacteria in the second edition) and kept at –20°C.

Taxonomy and Identification

The genealogical affiliation of four *Desulfotomaculum* species with the branch of Gram-positive bacteria with low GC content has been demonstrated by oligonucleotide cataloging (Fowler et al., 1985; Fig. 3) and by the sequencing (Devereux et al., 1989) of 16S rRNA. Comparative genealogical studies on *Desulfotomaculum* species on a larger scale are lacking thus far. Hence, it is not known whether there is a coincidence of physiological and phylogenetic groupings within the genus. The physiological variations in the genus (Table 1) and the relatively low degree of relatedness even between the nutritionally similar *D. orientis* and *D. ruminis* (Devereux et al., 1989; Chapter 183, Fig. 6) indicates that the genus is less coherent than any other genus of Gram-negative sulfate reducers. However, as long as the genus *Clostridium*, with its multiple physiological types, is not subdivided, there is no reason to do so with the genus *Desulfotomaculum*. For the present, sporeforming sulfate reducers can be unequivocally identified as members of the genus *Desulfotomaculum*. A brief description of characteristics of the genus is given in the following. Properties of particular species are listed in Table 1. Figures 1 and 2 show morphological features of a few species.

Genus *Desulfotomaculum*

The common property of *Desulfotomaculum* species is dissimilatory sulfate reduction to sulfide and the formation of endospores. The location of spherical or oval spores may be central, subterminal, or terminal. In some species, gas vacuoles

are formed simultaneously with spores (Daumas et al., 1988; Widdel and Pfennig, 1977, 1981; Fig. 1A). Spores are resistant to heat (80°C, 10 to 20 min), dryness, and oxic conditions. *Desulfotomaculum* species grow with H_2, alcohols, a few sugars, or simple organic acids including phenyl-substituted ones that serve as electron donors (Table 1). Some species oxidize organic electron donors incompletely to acetate. Species utilizing fatty acids or benzoate are capable of complete oxidation, even though these organic substrates may be partially converted to acetate (Daumas et al., 1988; Widdel and Pfennig, 1981). H_2-utilizing species may be capable of auto-trophic growth (Brysch et al., 1987; Daumas et al., 1988; Klemps et al., 1985; Min and Zinder, 1990; Nazina et al., 1988). In the absence of sulfate, some species grow by acid fermentation of glucose, fructose, or pyruvate. Certain *Desulfomaculum* species resemble homoacetogenic bacteria (see Chapter 21) in their ability to convert methanol, methoxyl groups of 3,4,5-trimethoxybenzoate, formate, and even H_2 and CO_2 to acetate (K. Hanselmann, personal communication; Klemps et al., 1985; Min and Zinder, 1990). This homoacetogenesis may allow weak growth in the absence of sulfate. Sulfite or thiosulfate can replace sulfate as electron acceptor in many species. *Desulfotomaculum* species are more sensitive toward the sulfide produced than most Gram-negative sulfate reducers. Whereas the latter often grow up to H_2S concentrations of around 20 mM, *Desulfotomaculum* species are inhibited by 7 to 10 mM H_2S. Desulfoviridin has never been found in the genus *Desulfotomaculum*; however, the sulfite reductase P582 is present, as shown by the characteristic carbon monoxide difference spectrum of reduced cell extracts (Trudinger, 1970; Widdel and Pfennig, 1977). It had originally been assumed that *Desulfotomaculum* species contain only cytochromes of the *b*-type, but *c*-type cytochromes have been detected as well (e.g., Daumas et al., 1988; Gogotova and Vainshtein, 1983; Jones, 1972).

CHAPTER 1.2.26

The Anaerobic Gram-Positive Cocci

TAKAYUKI EZAKI, NA LI AND YOSHIAKI KAWAMURA

Introduction

The anaerobic Gram-positive cocci (also known as peptococci and peptostreptococci) discussed in this chapter are limited to firmicutes with low mol% G+C. They are *Peptococcus*, *Peptostreptococcus*, *Anaerococcus*, *Peptoniphilus*, *Gallicola*, *Finegoldia*, *Micromonas*, *Ruminococcus*, *Coprococcus* and *Sarcina*. All except *Anaerococcus*, *Peptoniphilus*, *Gallicola*, *Finegoldia* and *Micromonas* belong to the classical family Peptococaceae (Rogosa, 1974). During the last 10 years, many members of the old genus *Peptostreptococcus* were transferred to many other genera. Most anaerobic Gram-positive cocci belong to the normal flora of the human gastrointestinal tract, vagina and oral cavity and often are found in human clinical specimens (Brook and Frazier, 1990; Ezaki et al., 1992). (Most human clinical isolates were identified as peptostreptococci.) Phylogenetically, anaerobic Gram-positive cocci belong to the phylum *Clostridium*. Indeed, based on 16S rRNA sequences, all species of the genus Peptostreptococcus (Li et al., 1994; Collins et al., 1994) were in different groups in this phylum. *Peptococcus niger* was close to the clostridial cluster III (Collins et al., 1994). *Sarcina ventriculi* was close to the clostridial cluster I (Li et al., 1994; Willems and Collins, 1994), and the ruminococci and coprococci were within clostridial cluster XIV (Willems and Collins, 1995; Rainey and Janssen, 1995).

Members of the genus *Peptostreptococcus* also were clustered into three groups within the phylum Clostridium: *P. anaerobius* within clostridial cluster XI, "*P. heliotrinreducens*," recently transferred to a new genus *Slackia* (a high mol% G+C firmicute; Wade et al., 1999), and the remaining species classified with clostridial cluster XIII.

Accumulated chemotaxonomic data also proved that peptostreptococci were in different groups. Old peptostreptococci have several peptidoglycan structures and their structures differ from that of the type species, *P. anaerobius* (Li et al., 1992; Murdoch et al., 1997). Using these data, peptostreptococci were recently reclassi-fied into five genera: *Anaerococcus*, *Peptoniphilus*, *Finegoldia*, *Micromonas* and *Gallicola*.

Habitat

Anaerobic cocci are part of the normal flora of the human oral cavity, alimentary tract, skin and vagina (Moore and Holdeman, 1974; Holdeman et al., 1986; Tanner and Stillmann, 1993). Among them, Micromonas micros and *Finegoldia magna* often are isolated from sites of oral infection and otorrhea (Shah and Gharbia, 1995). Sarcinae are isolated from soil but also from the digestive tract of humans and animals (Canale-Parola, 1970; Canale-Parola, 1986). The anaerococci, peptoniphili, peptostreptococci, finegoldiae and micromonades are found in the mouth and upper respiratory tract and in the lower small intestine, colon and vagina (Finegold and George, 1989; Murdoch, 1998; Tanner and Stillmann, 1993). *Ruminococcus obeum* and *R. bromii* are often isolated from the large intestine of humans (Moore et al., 1974). Anaerococci, peptoniphili and finegoldiae are frequently found in the vagina (Marui, 1981; Finegold, 1995). In particular, the species *Finegoldia magna*, *Peptoniphilus asaccharolyticus*, *Anaerococcus prevotii*, *A. hydrogenalis*, *A. tetradius*, *A. vaginalis*, *Ps. anaerobius*, *Peptococcus niger* and *Finegoldia magna* are common isolates from human skin (Wilkins and Jimenez-Ulate, 1975; Finegold, 1995). *Finegoldia magna*, *A. prevotii* and *P. asaccharolyticus* are also commonly in human and animal stools.

Anaerobic cocci have been known to be associated with sepsis, septic thrombophlebitis, puerperal fever, sinusitis and otitis media (Bartlett, 1993; Finegold, 1995). Early in the 20th century, anaerobic cocci or anaerobic streptococci were not referred to as true anaerobes. Capnophilic streptococci (anaerobic strains) were once placed in the genus *Peptococcus* and were later transferred to the genus *Streptococcus* (Holdeman and Moore, 1974). These include *S. intermedius*, *S. constellatus* and *S. anginosus*, and "*S. parvulus*" (now classified as *Atopobium parvulum*). *Staphylococcus saccharolyticus* (another

anaerobe), isolated from the skin (Evans et al., 1978), also was misidentified as true anaerobic cocci. Major Gram-positive anaerobic cocci isolated from various clinical specimens include members of the genus *Anaerococcus*, *Peptoniphilus*, *Finegoldia*, *Micromonas* and *Peptostreptococcus*, but not generally ruminococci, coprococci or sarcinae.

Isolation

Media for anaerobes should be stored under anaerobic conditions. Agar plates for the isolation of anaerobic cocci should be kept in anaerobic jars or chambers. The plates for ruminococci, coprococci and sarcinae should be kept under more reduced conditions. These organisms require carbohydrate to grow. Ruminococci and coprococci only grow in roll tubes or anaerobic chambers (such as anaerobic glove boxes) filled with a gas mixture of 80% nitrogen (N_2), 10% hydrogen (H_2) and 10% carbon dioxide (CO_2). Commercial gas is often contaminated with trace amounts of (O_2) oxygen; therefore, a palladium (Pd) catalyst should be placed in an anaerobic chamber to remove O_2. Because these chambers are O_2-free environments, they are useful, as well, for the isolation of O_2-sensitive bacteria. A rather inexpensive alternative to the anaerobic chamber method, the roll tube method (Hungate, 1966) was originally developed to isolate rumen bacteria and later modified by Holdeman et al. (1977). Broth and solid media are placed in tubes with rubber stoppers to prevent O_2 exposure. The media (called "prereduced anaerobically sterilized" [PRAS]) should be prepared under an O_2-free gas that is passed through a cold catalyst or heated copper catalyst. These PRAS agar plates and broth media are available commercially. Another culture technique for small clinical laboratories is the anaerobic jar method. One jar can hold from 10 to 20 agar plates. The jar (commercially available from e.g., Oxoid, Merck, BBL, or Mitsumishi Gas) includes a gas-generation bag, an O_2 indicator and a catalyst. For a single plate culture, an anaerobic pack, which is supplied with O_2-absorbing reagents and a CO_2 generator, is also commercially available (e.g., from Oxoid, Mitsubishi Gas or Dia Iatoron).

Primary Isolation Media for *Anaerobic Cocci* Not Requiring Fermentable Carbohydrates

Anaerobic cocci have complex growth requirements, which may include vitamins, cofactors and amino acids. Tween 80 (at a final concentration of 0.02%) enhances the growth of these organisms but is not required for their isolation. These cocci metabolize peptones and amino acids; therefore, a complex medium, such as blood agar or chopped meat medium, is necessary for isolation. Basal media for blood agar plates include Brucella agar (BBL), Schaedler agar (BBL), Colombia agar (Difco), and brain heart infusion agar; all basal media must be supplemented with yeast extract, vitamin K, hemin and 5% sheep's blood. Brucella HK agar (Kyokuto, Japan) is premixed with vitamin K and hemin. For the isolation of anaerobic cocci, media without blood, such as chopped meat agar, modified GAM agar (Nissui, Japan), ABCM agar (Eiken, Japan), and Brucella HK semisolid agar, are also useful. For the selective isolation of the anaerobic cocci from contaminated specimens, a phenylethyl alcohol blood agar (Difco, BBL) plate is recommended.

Isolation Media for *Ruminococci*, *Coprococci* and *Sarcinae*

Ruminococci (Bryant, 1986) and coprococci (Holdeman and Moore, 1986) require fermentable carbohydrates and ammonia for growth. Selective media for the primary isolation of these organisms have not been developed, except for the isolation of cellulolytic organisms. Unless special nutrients are added, currently available commercial media do not support growth, although ruminococci and coprococci grow well on media containing 30–40% rumen fluid.

Rumen Fluid-Glucose-Cellobiose Agar (Holdeman et al., 1977)

Glucose	0.25 g
Cellobiose	0.25 g
Soluble starch	0.5 g
$(NH_4)2SO_4$	1.0 g
Rumen fluid	300.0 ml
Cysteine-HCl · H_2O	0.5 g
Resazurin solution (see below)	4.0 ml
Salts solution (see below)	500.0 ml
Hemin solution (see below)	10.0 ml
Agar	20.0 g
Distilled water	186.0 ml

Rumen fluid can be replaced with a volatile fatty acid (VFA) mixture, as in medium 10 (see below; Caldwell and Bryant, 1966).

Resazurin Solution

Twenty-five mg of resazurin is dissolved in 100 ml of distilled water.

Salts Solution

$CaCl_2$	0.2 g
$MgSO_4$	0.2 g
$KIHPO_4$	1.0 g
KH_2PO_4	1.0 g
$NaHCO_3$	10.0 g
NaCl	2.0 g
Distilled water	1,000.0 ml

Hemin Solution

Fifty mg of hemin in 1 ml of 1 N NaOH is diluted up to 100 ml with distilled water.

Medium 10 (Caldwell and Bryant, 1966)

Trypticase (BBL)	2.0 g
Yeast extract (Difco)	0.5 g
Hemin solution	2.0 ml
Glucose	0.5 g
Cellobiose	0.5 g
Soluble starch	0.5 g
Agar	18.0 g
Resazurin	1.0 ml
0.69% K_2HPO_4	37.5 ml
Mineral solution 1	37.5 ml
VFA mixture	3.1 ml
L-Cysteine	10.0 ml
Na_2CO_3	50.0 ml
Ascorbic acid	2.0 ml
Distilled water	857.0 ml

Details of the preparation of the original Medium 10 are given in Holdeman et al. (1977).

Mineral Solution l

KH_2PO_4	0.6	g
$(NH_4)2SO_4$	0.6	g
NaCl	1.2	g
$MgSO_4 \cdot 7H_2O$	0.25	g
$CaCl_2 \cdot 2H_2O$	0.16	g

VFA Mixture

Acetic acid	17 ml
Propionic acid	6 ml
N-Butyric acid	4 ml
N-Valeric acid	1 ml
Isovaleric acid	1 ml
Isobutyric acid	1 ml
DL-a-Methylbutyric acid	1 ml

Selective isolation of cellulolytic ruminococci from rumen was established by Hungate (1966). Presumptive identification of cellulose digesters grown on rumen fluid-amorphous cellulose-agar plates is based on the appearance of typical colonies surrounded with a clear zone resulting from cellulose digestion.

Primary Isolation of Sarcinae

Selective media for the primary isolation of sarcinae are based on two distinct characteristics: 1) fermentable carbohydrates stimulate their growth and 2) they can grow at low pH (2.0–2.5). Sarcinae are often found in feces of humans when Bifidobacterium-selective medium, which contains tomato juice and maltose, is used.

Bifidibacterium Medium

Canned tomato juice	45.5 g
Maltose	10 g
Hemin solution	2 ml
Distilled water	600 ml

Adjust pH to 5–6.

A different medium is selective for sarcinae from soil.

Selective Enrichment Broth for the Isolation of Sarcinae from Soil (Canale-Parola, 1970)

Maltose	2.0 g
Malt extract broth (BBL)	5.0 g
Tap water	1,000 ml

Adjust to pH 2.2 with H_2SO_4.

Preservation of Cultures

Anaerobic cocci grow well in PRAS-chopped meat broth, GAM semisolid and Brucella HK semisolid medium.

PRAS-Chopped Meat Broth (Holdeman et al., 1977)

Ground beef (fat-free)	500 g
Distilled water	1,000 ml
1 N NaOH	25 ml

Boil the above mixture, then cool to room temperature. Skim off the fat and filter the broth. Add distilled water to restore to the original volume and add 30 g of trypticase, 5 g of yeast extract, 5 g of potassium phosphate, and 4 ml of 0.025% resazurin solution. Boil under O_2-free N_2 gas and add 0.5 g of cysteine, 10 ml of 0.05% hemin solution, and 1 µl of vitamin Kl solution. Adjust pH to 7.2 ± 0.2. Prepare the test tubes containing the meat particles (use one part meat particles to four to five parts fluid). Dispense 3–5 ml of the broth into the tubes filled with O_2-free CO_2 gas; seal the tubes with rubber stoppers, then autoclave.

Alternatively, because preparation of PRAS-chopped meat broth is time consuming, we often prepare semisolid GAM medium or modified semisolid Brucella medium (Kyokuto Seiyaku, Tokyo, Japan) in ordinary test tubes. *Anaerococci*, *Peptoniphili*, *Finegoldiae* and *Micromonades* grow well in this semisolid medium.

Modified Brucella Semisolid Medium for Maintenance of *Peptococci*, *Peptostreptococci*, *Finegoldiae* and *Micromonades*

Casein peptone	10.0 g
Beef peptone	10.0 g
Yeast extract	5.0 g
Soy peptone	4.0 g
Glucose	1.0 g
Sodium sulfite	0.1 g
Arginine	1.0 g
Vitamin K	1.0 µl
Hemin	0.01 g
Sodium pyruvate	1.0 g
Sodium fumarate	0.2 g
K_2HPO_4	0.4 g
KH_2PO_4	0.8 g
NaCl	2.5 g
Sodium thioglycolate	0.3 g
Soluble starch	5.0 g
Cysteine HCl	0.3 g
Agar	1.5 g
Distilled water	1,000 ml

These semisolid media can be used for at least one week after preparation. Indicators, such as resazurin, of oxygenated areas can be added to the semisolid media. For the maintenance of ruminococci, coprococci and sarcinae, semisolid PRAS-chopped meat medium supplemented with various carbohydrates (Holdeman et al., 1977) is recommended. The rubber stopper of the test tube is opened without flushing the inside of the tube with gas. After inoculation of the organisms with a Pasteur pipette, the test tube should be sealed with a rubber stopper. Most ruminococci and coprococci may grow in this way, but they grow better if the tube is filled with a gas mixture (N_2, 80%; CO_2, 10%; H_2, 10%). Brucella HK and GAM semisolid media support the growth of most anaerobic cocci. *Peptococcus niger* grows poorly in these commercial media, but the addition of pyruvic acid will stimulate the growth. *Ruminococci* and *coprococci* also grow poorly in Brucella HK and GAM, and so they are maintained in PRAS-chopped meat broth supplemented with fermentable carbohydrate (glucose, cellobiose or maltose at a concentration less than 0.2%). Sarcinae will die within one week in acidic enrichment broth. These anaerobic cocci are viable for at least several years at −80°C or in liquid nitrogen.

Basal Media for Identification

Pre-reduced peptone-yeast extract (PY) medium (Holdeman et al., 1977) is used for the characterization of anaerobic cocci. Most anaerobic cocci grow poorly in this medium. Thus a heavy inoculum of a young culture (5% of broth culture) is critical in this procedure. Commercial pre-reduced PY medium (Scot II) based on the description by Holdeman et al. (1977) is available.

Basal Prereduced Peptone-Yeast Extract (PY)
Medium (Holdeman et al., 1977)

Trypticase	5.0 g
Peptone	5.0 g
Yeast extract	10.0 g
Vitamin K1	1.0 µl
Hemin	5.0 g
Cysteine HCl	0.5 g
Salts solution	40.0 ml
Distilled water	960.0 ml

Identification

Phylogenetic Position of Anaerobic Gram-positive Cocci

Members of the family *Peptococaceae* (Rogosa, 1974) previously were divided into five phylogenetic groups in the phylum *Clostridium*. *Clostridia*, viewed as mixtures of phylogeneti-cally different organisms, were assigned to 19 phylogenetic groups (Collins et al., 1994). In this study, anaerobic cocci and many species of genus *Eubacterium* were found to be in the phylum *Clostridium*. *Peptococcus niger* was included in clostridial cluster III (Collins et al., 1994). *Sarcina ventriculi* was found to cluster closely with clostridial cluster I (Li et al., 1994; Willems and Collins, 1994), and ruminococci and coprococci with clostridial cluster XIV (Willems and Collins, 1995; Rainey and Janssen, 1995). Members of the genus *Peptostreptococcus* were in three different clostridial clusters. For example, *P. anaerobius* was in clostridial cluster XI. "*P. heliotrinreducens*" was recently transferred to a new genus *Slackia* (Wade et al., 1999). Chemotaxonomic data also proved that peptostreptococci grouped differently. Peptostreptococci have several different peptidoglycan structures, all of them different from that of the type species, *P. anaerobius* (Li et al., 1992; Murdoch et al., 1997). Taken together, the evidence suggested that five genera—*Anaerococcus*, *Peptoniphilus*, *Gallicola*, *Finegoldia* and *Micromonas*—be proposed (Murdoch and Shah, 1999; Ezaki et al., 2000). Thus, only the type species Peptostreptococcus anaerobius remained in the genus *Peptostreptococcus*. Their biochemical characteristics at genus level are shown in Fig. 1.

In the early 1970s, Rogosa (1971) proposed the family Peptococcaceae to which the genera *Peptococcus*, *Peptostreptococcus*, *Ruminococcus* and *Sarcina* were assigned. Later, Holdeman and Moore (1974) added the new genus *Coprococcus*. However, phylogenetic analysis of 16S rRNA of members of this family revealed that they were scattered in the phyla of Firmicutes with low mol% G+C (Fig. 2). Type species of the genus *Peptostreptococcus*, *P. anaerobius* was independent from other members of the genus *Peptostreptococcus* and clustered with clostridial cluster IX (Collins, 1994). Asaccharolytic and butyrate-positive group 1 peptostreptococci were now reclassified as genus *Peptoniphilus*. Weakly saccharolytic and butyrate-producing group 2 peptostreptococci were reclassified as genus *Anaerococcus*. Three species of group 3 peptostreptococci that carried different peptidoglycan structures were assigned to genera *Finegoldia*, *Micromonas* (Murdoch and Shah, 1999) and Gallicola (Ezaki et al., 2000). Their phylogenetic relationship is shown in Fig. 2.

Members of the genus *Ruminococcus* were clearly divided into two groups. Group 1 contains the type species, *R. flavefaciens*. Group 2 ruminococci and coprococci were grouped into clostridial cluster XIVa (Fig. 2). Packet-forming cocci, the sarcinae, were found to be close to *Clostridium perfringens*. Differential characteristics of these groups at genus level are listed in Table 1.

Fig. 1. Phylogenetic position of anaerobic cocci among firmicutes with low mol% G+C.
Fig. 2. Phylogeny of Gram-positive anaerobic cocci.

Identification

Biochemical Identification

The first step in the identification of anaerobic cocci is to distinguish anaerobic strains of streptococci and staphylococci from "true anaerobic cocci." *Streptococcus pleomorphus* is anaerobic and strains of *Gemella morbillorum* (Kilpper-Baelz and Schleifer, 1988), *S. anginosus*, *S. intermedius* and *S. constellatus* often grow only under strictly anaerobic conditions but most of them, after several transfers in the laboratory, eventually grow in an O$_2$-reduced environment or in a 5–10% CO$_2$ incubator. Anaerobic strains of streptococci and gemellae, unlike *Peptococcus*, *Peptostreptococcus*, *Ruminococcus*, *Coprococcus*, *Finegoldia*, *Micromonas*, *Gallicola* and *Sarcina*, solely produce lactic acid from PY medium containing glucose.

Colonies of *Staphylococcus saccharolyticus*, a species formerly assigned to the genus *Peptococcus*, often grow on anaerobic plates under reduced O$_2$ conditions (e.g., in a 5–10% CO$_2$ incubator; Evans et al., 1978) or more slowly in aerobic primary culture. *Staphylococcus aureus* subsp. anaerobius (Fuente et al., 1985) also grows under reduced O$_2$ conditions but it is more aerotolerant than *S. saccharolyticus*. Thus, differentiating *S. saccharolyticus* from other anaerobes is difficult when growth has only been attempted in anaerobic conditions. Like finegoldiae and

micromonades, *Staphylococcus saccharolyticus* produces acetic acid as a major metabolic product from PYG medium and thus must be differentiated from them. Simple biochemical tests, such as the nitrate reduction test and the urease test, are useful in this regard.

Differentiation of Anaerobic Cocci

Table 1 shows genus-level features used to differentiate anaerobic Gram-positive cocci. Anaerococci, peptoniphili, gallicolae, finegoldiae, micromonades, peptostreptococci, and peptococci use peptones as their major energy sources, and carbohydrates are not required for their growth. On the other hand, ruminococci, coprococci and sarcinae require carbohydrate for their confluent growth. Species-level differentiation of peptone-digesting organisms that require carbohydrates for their growth are shown in Tables 2 and 3. Species in Table 2 can be differentiated from ruminococci, coprococci and sarcinae because peptones (but in most cases not carbohydrates) are their major energy sources. *Peptoniphilus* spp. can be differentiated from peptostreptococci and peptococci because *Peptoniphilus* produces butyrate but not capronate from PYG medium.

 Peptococcus asaccharolyticus is often isolated from human clinical specimens and are a part of normal flora of the human vagina and gastrointestinal tract (Bartlett, 1990; Hill et al., 1995;

Hillier et al., 1993; Hillier and Moncla, 1991). However, this species contains many different genotypes (Ezaki et al., 1983; Ezaki et al., 1992). This suggests that the biology and pathogenicity of this species is not well defined. The identification of *P. asaccharolyticus* is controversial. *Peptoniphilus asaccharolyticus* should be differentiated from other indole-positive species *P. hydrogenalis*, *A. indolicus*, and *A. harei*. In spite of the phenotypic similarity between *A. indolicus* and *P. asaccharolyticus* (both are strongly saccharolytic and have weak proteolytic enzyme activities), the coagulase and positive nitrate reduction tests often help differentiate the two species. However, some *P. asaccharolyticus* reduce nitrate.

Strains of *P. hydrogenalis* are strongly saccharolytic and produce indole. Their proteolytic enzyme activity is very weak as shown in Table 2. They were isolated from human feces and vaginal discharge (Ezaki et al., 1992).

Peptococcus indolicus is isolated from lesions and abscesses of sheepherders, rarely from other human specimens (Bourgault and Rosenblatt, 1979), and from cows with bovine summer mastitis (Hoi-Sorenson, 1973; Madsen et al., 1992). Although biochemically similar to *P. asaccharolyticus*, *P. indolicus* produces coagulase, reduces nitrate to nitrite, and forms propionate from lactate (Holdeman et al., 1977). Species are proteolytic and do not ferment sugars.

Peptococcus lacrimalis was first isolated from the human lacrimal gland (Li et al., 1992) and

identified as "*P. prevotii*" (now called *A. prevotii*) because it did not produce indole. However, 16S rRNA and DNA/DNA hybridization analyses revealed a new species. Its biochemical characteristics are similar to anaerococci, except that it does not ferment carbohydrate.

Peptococcus harei was first reported as "*Peptostreptococcus harei*" (Murdoch and Mitchelmore, 1991) and isolated from various skin abscesses (Murdoch et al., 1997). Some strains produce indole and catalase. All strains are asaccharolytic and moderately proteolytic.

Peptococcus ivorii, first isolated from human leg ulcers and clinical specimens (Murdoch et al., 1997), is asaccharolytic and weakly proteolytic. Because it produces minor amounts of isovaleric acid, isolates can be misidentified as *Peptostreptococcus anaerobius*.

Anaerococcus spp. produce weak acids from several carbohydrates but they also use peptones as their energy source. As a result, they produce butyrate from PYG medium.

Anaerococcus prevotii were recognized as the only indole-negative and butyrate-positive anaerobic Gram-positive cocci until the early 1990s (Holdeman et al., 1986) when six other species (isolated from vaginal discharges, and ovary and skin abscesses) were described (Ezaki et al., 1983; Murdoch et al., 1997; Ezaki et al., 2000) as saccharolytic and proteolytic. *Anaerococcus tetradius*, previously classified as "*Gaffkya anaerobica*," was transferred to the genus *Peptostreptococcus* (Ezaki et al., 1983). However, after 16S rRNA analysis, its reclassification as a member of the genus *Anaerococcus* (Ezaki et al., 2000) was proposed. Like *A. prevotii*, *A. tetradius* has saccharolytic and proteolytic activity. Only a few biochemical tests are able to differentiate the two species. *Anaerococcus tetradius* is a vaginal microorganism, also isolated from ovarian and other abscesses.

Anaerococcus vaginalis was isolated from vaginal discharges (Li et al., 1992). A weakly saccharolytic species, its proteolytic enzymes and sugar fermentation patterns are generally useful for differentiating these organisms from other anaerococci.

Anaerococcus hydrogenalis is a strongly saccharolytic species. It is also isolated from vaginal discharge and stool from humans (Ezaki et al., 1990). Gas production from PYG is very strong and often a test tube with rubber stopper will explode. Indole production is positive.

Anaerococcus lactolyticus, isolated from the human vagina and the gastrointestinal tract (Li et al., 1992), is weakly saccharolytic, weakly proteolytic and urease positive. *Anaerococcus octavius*, isolated from the nasal cavity (Murdoch et al., 1997), is weakly saccharolytic and produces a small amount of capronate from PYG.

Finegoldia magna is an anaerobic cocci frequently isolated from human clinical specimens (Bourgault et al., 1980; Brook, 1981; Brook, 1988; Brook, 1989; Brook, 1995; Brook, 1996), including ovarian, peritoneal and skin abscesses (Brook, 1988; Hunter and Chow, 1988; Finegold, 1995). The organism was recently transferred from the genus *Peptostreptococcus* (Murdoch and Shah, 1999). *Finegoldia magna* does not produce butyrate but rather acetate as a major metabolic end product from PYG. No carbohydrates are fermented. Although phenotypically related to *Micromonas micros*, *F. magna* cells are 0.8 to 1.9 µm and *M. micros* cells are 0.3 to 0.7 µm.

Micromonas micros was once a member of the genus *Peptostreptococcus* (Murdoch and Shah, 1999). It is among the normal flora of the oral cavity (Murdoch et al., 1988). All strains have a strong alkaline phosphatase activity (Ezaki and Yabuuchi, 1985), whereas only some *F. magna* strains have alkaline phosphatase activity, which is usually very weak. Strains of *F. magna* from various sources were genetically identical (T. Ezaki, unpublished observation), but *M. micros* reportedly has two morphotypes (Van Dalen, 1993).

Peptostreptococcus anaerobius now is the only species in the genus. It is isolated from stool samples and the vagina. The cells are usually coccobacilli and highly pleomorphic. Isocapronate and isovalerate are major metabolic end products. On the basis of the coccobacillus morphology and pattern of metabolic products, it is often misidentified as clostridium. The species is also clustered in the clostridium XI group (Collins et al., 1994).

Peptococcus niger has been isolated from human urine (Hall, 1930), the umbilicus (Wilkins et al., 1975) and the vagina (Marui, 1981). Initially black colonies form on blood agar plates, but after successive culture on a blood agar, gray colonies form, that is to say if they form at all. Capronate production from PYG (Holdeman et al., 1986) is a characteristic. Sugars are not fermented and proteolytic enzyme activity is not detected.

Gallicola barnesiae originally was isolated from chicken feces (Schiefer-Ullrich and Andreesen, 1985). The other sources are not clearly identified. It is asaccharolytic and feebly indole positive.

Differentiation of ruminococci, coprococci and sarcinae

Differential characteristics of ruminococci, coprococci and sarcinae are shown in Table 3.

Growth of ruminococci and coprococci is remarkably enhanced by rumen fluid (Holdeman and Moore, 1974). The two genera can be

differentiated on the basis of formate, acetate and lactate, which are produced from PYG by ruminococci and butyric acid, which is produced from PYG by coprococci. Ruminococci are divided into two phylogenetic groups (Fig 2). The second group of ruminococci and the coprococci are in the same phylogenetic group. Species in the genus *Ruminococcus* and *Coprococcus* are normal flora of the human and animal gastrointestinal tract (Bryant, 1986).

Ruminococus productus (formerly *Peptostreptococcus productus*; Ezaki et al., 1994) ferments various carbohydrates and produces lactate and acetate from PYG.

Ruminococcus hansenii was once classified as *Streptococcus hanseni* (Holdeman and Moore, 1974) because the major metabolic end product was lactate. However, the species (an obligate anaerobe) was phylogenetically a member of the genus *Ruminococcus* (Ezaki et al., 1994). It has strong saccharolytic activities and occasionally is isolated from human clinical specimens (Marui, 1981).

Sarcinae have characteristic packet morphology and can form spores. Organisms have been found in the gastric contents and feces of patients with gastric disorders (Crowther, 1971), and they are common in the soil and the stool of vegetarians (Ezaki et al., 1994; Crowther, 1971).

Sarcina maxima and *S. ventriculi* can be differentiated by their metabolic end products, the former producing butyric acid and the latter formate and acetate.

Molecular Identification of Anaerobic Cocci

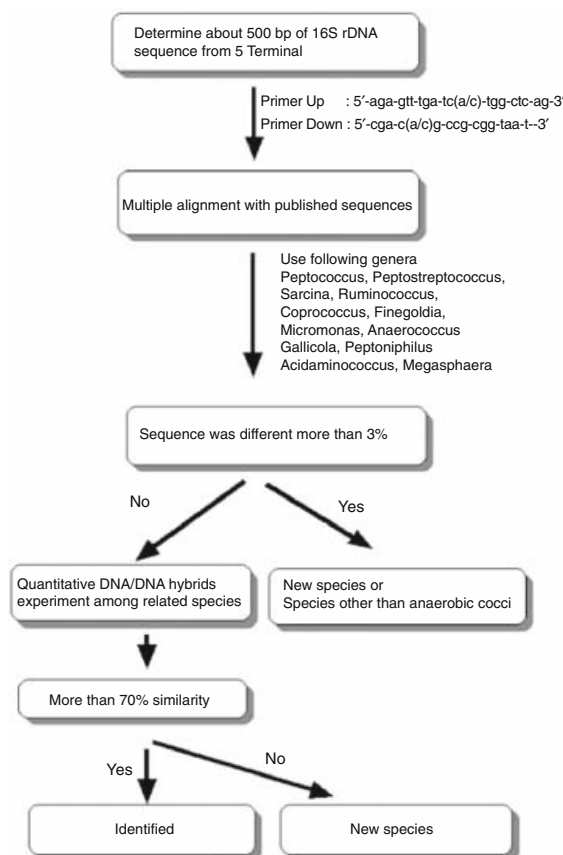
Biochemical differentiation of anaerobic cocci is technically demanding and often unsuccessful because of their fastidious growth in chemically defined media. On the other hand, almost all 16S rDNA sequences of anaerobic cocci have been determined. Determining the phylogenetic position of anaerobic cocci (Fig. 3) is much easier than biochemical characterization. The following scheme is also applicable for molecular identification of all bacteria. First, determine the partial 16S rDNA sequence of unidentified anaerobic cocci. Amplify the 16S rDNA with two universal primers (16S-up: 5′-AGA-GTT-TGA-TC(A or C)-TGG-CTC-AG-3′ and 16S-down: 5′-CAG-C (A or C)G-CCG-CGG-TAA-T-3′). A PCR product of approximately 500 bp will be amplified. For the phylogenetic analysis, a full-range sequence is essential but a partial sequence is usually enough for identification. The next step is FAST or Basic Local Alignment Search Tool (BLAST) analysis through the DNA Databank of Japan (DDBJ), Gene Bank or European Molecular Biology Laboratory (EMBL) to find related sequences. If the organism is truly an


Fig. 3. Identification scheme for anaerobic cocci.

anaerobic cocci, sequences of the species listed in Table 1 would be picked up from the above databases.

After preparing a data set of the related species, run multiple alignments with software Clustal W (Thompson, 1994). If the similarity values between the examined strain and the closest species are smaller than 97%, the examined strain might be a new species. If the similarity value is higher than 97%, then perform quantitative DNA/DNA hybridization among related species (Stackebrandt and Goebel, 1994a). Quantitative DNA/DNA hybridization values higher than 70% among the closest strains means that the two species are taxonomically identical (Johnson, 1984; Wayne et al., 1987). Simple quantitative DNA/DNA hybridizations can be done in 96-well microtiter plates (Ezaki et al., 1989; Shatha et al., 1993; Cristensen et al., 2000).

Antibiotic Susceptibility

Anaerobic cocci usually are sensitive to all the antibiotics commonly used to treat anaerobic infections (Finegold and George, 1989; Garcia-Rodriguez et al., 1995; Murdoch, 1998). Rou-

tine susceptibility testing for anaerobes is not required. Most evidence suggests that *P. asaccharolyticus*, *F. magna*, *M. micros* and *A. prevotii* are almost always susceptible to the penicillins (Bowker et al., 1996; Johnson, 1993). Of the cephalosporins, cefoxitin is probably the most effective (Murdoch, 1998). Cefotaxime often appears to have borderline activity (Murdoch, 1998; Citron et al., 1995; Panichi et al., 1990).

Metronidazole usually is effective (Watt and Smith, 1990). Microaerophilic streptococci, often misidentified as true anaerobic cocci, are resistant to metronidazole. For this reason, true anaerobic cocci are often misunderstood to be resistant to metronidazole. Nevertheless, some isolates of *Ps. anaerobius* are moderately resistant to metronidazole (Bowker et al., 1996).

Erythromycin, clarithromycin and azithromycin are probably not effective enough to be recommended for treatment (Brudoch, 1998; Sanchez et al., 1992). Teicoplanin and vancomycin are effective (Greenwood and Palfreyman, 1987). Several studies indicate that first generation quinolones have only moderate antibacterial activity against the anaerobic cocci; however, a recent study indicates that anaerococci, peptoniphili, finegoldia, and micromonades are consistently highly susceptible to trovafloxacin and clindafloxacin (Murdoch, 1998). Only isolates of *Ps. anaerobius* are often borderline and resistant (Murdoch, 1998). Carbapenems are extremely active, and new quinolones are also very effective.

Wilkins and Chalgren (1976) worked out techniques for the determination of minimum inhibitory concentration (MIC). The medium developed supports the growth of anaerococci, peptoniphili, finegoldiae, and micromonades, but most isolates of ruminococci, coprococci and sarcinae do not grow on the medium. Standard procedures to determine antibiotic susceptibility of anaerobes were published (Finegold and NCCLS, 1988; US standard, National Committee for Clinical Laboratory Standards, 1990; UK standard, British Society for Antimicrobial Chemotherapy, 1991).

CHAPTER 1.2.27

The Order Haloanaerobiales

AHARON OREN

Introduction

Bottom sediments of hypersaline lakes and lagoons may be expected to support a rich community of anaerobic halophilic bacteria, as the solubility of oxygen in hypersaline brines is low and the amounts of organic matter available are often high (Oren, 1988). Therefore, it is surprising that the first records of obligatory anaerobic fermentative bacteria growing at salt concentrations of 10–20% and higher appeared only in the early 1980s, when *Haloanaerobium praevalens* was isolated from the bottom sediments of the Great Salt Lake in Utah (Zeikus, 1983; Zeikus et al., 1983) and *Sporohalobacter lortetii* and *Halobacteroides halobius* were discovered in Dead Sea sediments (Oren, 1983; Oren et al., 1984b). *Haloanaerobium praevalens* may be similar to "*Bacteroides halosmophilus*," isolated by Baumgartner, 1937 from solar salt and from salted anchovies, but unfortunately no cultures of that isolate have been preserved.

The fermentative obligatory anaerobic halophilic Bacteria appear to be a phylogenetically coherent group (Rainey et al., 1995). The order Haloanaerobiales was created to accommodate these halophilic anaerobes. At the time of writing (January 1999), 19 species had been described and classified in two families, the Haloanaerobiaceae (Oren et al., 1984a; Rainey et al., 1995) and the Halobacteroidaceae (Rainey et al., 1995). This chapter presents these species and discusses their properties. The group was earlier reviewed by Lowe et al., 1993, Ollivier et al., 1994, and Oren, 1986a, Oren, 1990, Oren, 1993a, Oren, 1993b.

Phylogeny

Phylogenetic analysis based on 16S rRNA gene sequences has shown that the 19 obligatory anaerobic halophilic bacteria validly described thus far, may be classified in a single order, the Haloanaerobiales (Rainey et al., 1995), with two families, the Haloanaerobiaceae (Oren et al., 1984a) and the Halobacteroidaceae (Rainey et al., 1995) (Table 1, Fig. 1). Figures 2–3 present

micrographs and electron micrographs of selected species.

All isolates share a low content of G+C in their DNA. With the exception of the thermophilic *Halothermothrix orenii*, which has a G+C content of 39.6 mol%, all species have G+C contents between 27 and 36.9 mol%.

Based on 16S rRNA gene sequences, the halophilic anaerobic bacteria should be classified in the domain Bacteria within the phylum of the Gram-positive bacteria. They form a coherent cluster close to the bifurcation point that separates the Actinomycetes subphylum and the *Bacillus/Clostridium subphylum*. Sequences of the halophilic anaerobes contain all of the few signature nucleotides that have been defined as characteristic of members of the *Bacillus/Clostridium subphylum*, while they lack any of the Actinomycetes-specific nucleotides. Therefore, the halophilic anaerobes were suggested to be in the *Bacillus/Clostridium subphylum* (Patel et al., 1995; Rainey et al., 1995; Tourova et al., 1995). The phylogenetic affiliation of *Haloanaerobium praevalens* with the *Bacillus/Clostridium* group was confirmed by the amino acid sequence of its ribosomal A-protein (Matheson et al., 1987). The location of the branching point of the halophilic anaerobes close to the root of this subphylum is further evidence that certain descendants of the ancestors of the Gram-positive bacteria still maintained their Gram-negative wall type, as is the case with *Sporomusa* and relatives. The deep branching justifies classification in a separate order, and thus the order Haloanaerobiales was created (Rainey et al., 1995). Table 2 presents the signature nucleotides defining the Haloanaerobiales within the *Bacillus/Clostridium subphylum* of the Gram-positive Bacteria. The 16S rRNA signature nucleotides defining the two families are shown in Table 3.

Taxonomy

The properties of the species assigned to the families Haloanaerobiaceae and Halobacteroidaceae are summarized in Tables 4–5, respectively.

All species show a negative Gram stain reaction. Electron micrographs of thin sections generally show a typical Gram-negative type of cell wall with a prominent outer membrane and periplasmic space (see e.g., Figs. 3B, D, E, and G). The presence of meso-diaminopimelic acid in the peptidoglycan has been documented in *Haloanaerobium saccharolyticum* (Zhilina et al., 1992b).

A number of species of the Haloanaerobiales have been shown to produce heat-resistant endospores. These include *Sporohalobacter lortetii* (Oren, 1983), *Orenia marismortui* (Oren et al., 1987), and *Natroniella acetigena* (Zhilina et al., 1996). When initially isolated, *Acetohalobium arabaticum* produced sometimes spores, but with continued cultivation, sporulation was no longer observed (Zavarzin et al., 1994).

Habitat

Members of the Haloanaerobiales have been isolated from a wide variety of anaerobic hyper-

Table 1. Taxonomic structure of the order Haloanaerobiales.

Order Haloanaerobiales	
Family Haloanaerobiaceae	Family Halobacteroidaceae

Figures were derived from Oren et al., 1984b, Cayol et al., 1994b, Cayol et al., 1994a, Cayol et al., 1995, and Oren, 1983 respectively; reproduced with permission.

Table 2. 16S rRNA signature nucleotides defining the Haloanaerobiales within the *Bacillus/Clostridium subphylum* of Gram-positive bacteria (from Rainey et al., 1995; reproduced with permission).

Position E. coli nomenclature	Haloanaerobiales (>90% of species)	Majority of the members of the *Clostridium/Bacillus* subphylum (>90%)
94	one-base insertion	no insertion
771–808	U-A	G-C
772–807	R-Y	U-A
784–798	G-C	A-U
890	mainly U	G
1059–1198	mainly C-G	U-A
1115	mainly C	U
1415–1485	Y-R	G-U

Y = pyrimidine; R = purine.

saline environments. Fermentative halophilic bacteria have been recovered from: the Great Salt Lake, in Utah (Tsai et al., 1995; Zeikus et al., 1983); Salton Sea in California (Shiba, 1991; Shiba and Horikoshi, 1988; Shiba et al., 1989); the Dead Sea (Oren, 1983; Oren et al., 1984b; 1987); a hypersaline sulfur spring on the shore of the Dead Sea (Oren, 1989); oil wells and petro-leum reservoir fluids (Bhupathiraju et al., 1991, 1993, 1994, 1999; Ravot et al., 1997; Rengpipat et al., 1988a); hypersaline lakes and lagoons in the Crimea (Simankova et al., 1993; Zhilina and Zavarzin, 1990a; Zhilina et al., 1991, 1997) and in Senegal (Cayol et al., 1994a, 1995); saltern ponds in California (Liaw and Mah, 1992) and France (Mouné et al., 1999); a hot hypersaline lake in Tunisia (Cayol et al., 1994b); and the alkaline hypersaline lakes, Magadi, in Kenya (Shiba and Horikoshi, 1988; Zhilina et al., 1996) and Big Soda Lake in Nevada (Shiba and Horikoshi, 1988; Shiba et al., 1989). Thus, the range of habitats includes both thalassohaline and athalassohaline environments.

Isolation

Any anoxic reducing medium containing high salt concentrations (5–25%) and containing a suitable carbon source is a potential enrichment and growth medium for anaerobic halophilic bacteria. A variety of such media have been used for the growth and isolation of different members of the *Haloanaerobiales*. Table 6 presents a selection.

Y = pyrimidine; R = purine; ND = no data available.

The Haloanaerobiales are obligate anaerobes. Though they are not extremely sensitive to molecular oxygen, the use of strict anaerobic techniques is recommended, including boiling the media under nitrogen or nitrogen-CO_2 (80 : 20), and adding reducing agents such as cysteine, dithionite, or ascorbate to the boiled media.

The existence of heat-resistant endospores has been exploited in a selective enrichment procedure for *Halobacteroides halobius*-like bacteria, based on negative selection by pasteurization of the inoculum for 10–20 min at 80–100°C (Oren, 1987).

Identification

Identification of isolates and their assignment to one of the recognized genera and species of the Haloanaerobiales should be based preferentially on the determination of their 16S rRNA gene sequences. In addition, phenotypic characterization should be performed and the properties of the strains should be compared with those of the described species (Tables 4–5). Their ability to grow on different carbohydrates and other simple compounds can be used often to differentiate between the species. Identification should be based on a full phenotypic characterization and not on a few selected properties only. For example, chitinolytic activity is a poor characteristic for differentiating *Haloanaerobacter chitinovorans* from other anaerobic halophiles, as only one of the two strains described, which share 92.3% DNA-DNA homology, degrades chitin (Liaw and Mah, 1992; Rainey et al., 1995).

The members of the Haloanaerobiales can be divided into three groups on the basis of the substrates fermented. Most species are able to ferment a variety of carbohydrates. One species, *Sporohalobacter lortetii*, seems to be primarily an amino acid fermenter, and sugars are used only poorly (Oren, 1983). Serine can be used as electron donor in the Stickland reaction by *Haloanaerobacter salinarius* with glycine betaine as electron acceptor, with formation of acetate, trimethylamine, CO_2, and NH_3 (Mouné et al., 1999). Finally, the neutrophilic *Acetohalobium arabaticum* and the alkaliphilic *Natroniella acetigena* are homoacetogens, which do not use carbohydrates but grow chemoheterotrophically on substrates such as lactate, ethanol, pyruvate, glutamate, propionate, and glycine betaine, or chemoautotrophically on hydrogen + carbon dioxide (*Acetohalobium* only), producing acetate (Zavarzin et al., 1994; Zhilina and Zavarzin, 1990a, 1990b; Zhilina et al., 1996).

The property of endospore formation may be expressed only under special conditions, especially on solid growth media or in nutrient-poor liquid media (Oren, 1983; Oren et al., 1987). Certain representatives make spores only rarely, e.g., *Natroniella acetigena* (Zhilina et al., 1996) and *Acetohalobium arabaticum*. The latter is reported to produce spores when originally isolated but loses this property upon continued cultivation (Zavarzin et al., 1994). A phenotypic test, which may be correlated with the phylogenetic position of the Haloanaerobiaceae within the phylum of the Gram-positive Bacteria and with the ability to form endospores, is the hydrolysis of the D-isomer of N′-benzoyl-arginine-p-nitroanilide (BAPA). Four representatives of the Haloanaerobiales were tested for D-BAPA and

L-BAPA hydrolysis, and three of them (*Halobacteroides halobius*, *Haloanaerobium praevalens*, *Orenia marismortui*) were found to hydrolyze D- but not L-BAPA. *Sporohalobacter lortetii* degraded neither of the BAPA stereoisomers (Oren et al., 1989).

Preservation

Several species of the *Haloanaerobiales*, notably *Halobacteroides halobius* (Oren et al., 1984b), *Orenia marismortui* (Oren et al., 1987), *Haloanaerobacter chitinovorans* (Liaw and Mah, 1992), *Haloanaerobacter lacunaris* (Zhilina et al., 1992a), *Haloanaerobacter salinarius* (Mouné et al., 1999), and *Natroniella acetigena* (Zhilina et al., 1996) easily undergo autolysis, during which spherical degeneration forms can be observed (see Figs. 1 B, C). Lysis starts at the end of the exponential growth phase, especially at relatively high growth temperatures. One possibility to avoid death of such cultures is the use of media with a reduced nutrient content and of lower growth temperatures (15–25°C). Weekly transfers may then suffice to maintain viable cultures.

The surest way to maintain cultures is by lyophilization, and so they are maintained by culture collections. *Haloanaerobium acetoethylicum* was successfully preserved by freezing anaerobic suspensions in 20% glycerol at –80°C (Rengpipat et al., 1988a).

Table 6. Media for the growth of members of selected members of the Haloanaerobiales (all values in g/liter, unless stated otherwise). Additional information can be found in the original species description papers at the Deutsche Sammlung von Mikroorganismen und Zellkulturen (http://www.dsmz.de/media/media.htm).

Physiology

All members of the Haloanaerobiales are strict anaerobes. They are oxidase and catalase-negative, and they do not contain cytochromes.

Most species grow fermentatively on sugars, producing acetate, ethanol, hydrogen, and carbon dioxide. Some strains produce in addition butyrate, lactate, propionate, and formate. *Haloanaerobium congolense* does not form ethanol (Ravot et al., 1997). The glucose transport system of certain Halobacteroides strains has been characterized in part (Senyushkin et al., 1992; Severina et al., 1992). Glycine betaine fermentation by *Haloanaerobium alcaliphilum* yields acetate and trimethylamine (Tsai et al., 1995). *Acetohalobium arabaticum* in pure culture accumulates little trimethylamine, as most is converted to acetate. In coculture with halophilic methanogenic bacteria, most trimethylamine formed is utilized by the methanogens (Zhilina and Zavarzin, 1990a).

Acetohalobium arabaticum and *Natroniella acetigena* have a homoacetogenic metabolism, producing acetate as the main end product of their energy metabolism. *Acetohalobium arabaticum* can grow on hydrogen + carbon dioxide or on carbon monoxide as a lithoautotroph, on trimethylamine as a methylotroph, and on other substrates (formate, trimethylamine, glycine betaine, lactate, pyruvate, histidine, aspartate, glutamate, and asparagine) as an organotroph (Kevbrin et al., 1995; Zhilina and Zavarzin,

1990a, 1990b). Electron transport from hydrogen during autotrophic growth is mediated by a flavoprotein, without involvement of NAD, cytochromes or quinones (Pusheva and Detkova, 1996; Pusheva et al., 1992). Activity of a Na^+/H^+ antiporter was shown to be important in the energy metabolism of this bacterium. Monensin, an inhibitor of Na^+/H^+ antiport and Na^+-dependent ATP synthesis, inhibited growth, and it was postulated that the Na^+ potential generated via Na^+/H^+ antiport is essential for the functioning of the cell (Pusheva and Detkova, 1996). The corrinoid metabolism of this organism has been studied as well (Bykhovsky et al., 1994).

All known members of the Haloanaerobiales can be classified as moderately halophilic. Most grow optimally at NaCl concentrations around 10–15%. A minimal NaCl concentration of 2–10% is required, depending on the species, and NaCl concentrations of up to saturation support growth in certain isolates. The most halophilic representative described thus far is *Haloanaerobium lacusrosei*, which grows between 6 and 34% NaCl with an optimum at 20% (Cayol et al., 1995).

Although belonging to the bacterial domain, the representatives of the order Haloanaerobiales display a number of physiological and biochemical properties characteristic of the halophilic Archaea rather than of the moderately halophilic aerobic Bacteria. Whereas the halophilic Bacteria (aerobes as well as anaerobic photosynthetic types) accumulate organic
